PREFACE.

THE cordial reception given the *Year-Book* of 1896 has stimulated the editors to renewed enthusiasm in the preparation of the present volume, and encourages us to believe that the plan and execution of the work meet a clear professional want.

A few changes will be noted in the names of those in charge of some of the departments. The pressure of professional work forced Dr. Hardaway to resign the editorship of the department of Dermatology, and it was with great reluctance that I was compelled to admit that his excuse was ample and just. Readers will be glad that Dr. Duhring, whose rank as a scientist in his specialty needs no word of emphasis, has consented to assume the editorship. The other editorial changes were made for reasons similar to those of Dr. Hardaway. In the main, however, the editorial staff remains the same as that of the issue of 1896.

A noteworthy and, I believe, a useful feature of the present volume consists in the brief recapitulations of the trend and results of the year's work preceding each article.

The activity of scientific investigation and progress and the tremendous quantity of the literature to be reviewed, sifted, and judicially pronounced upon have necessitated a most rigorous choosing and condensation—a labor which only unselfish and enthusiastic workers can accomplish. The generous loyalty of the departmental editors cannot be too highly appreciated by those who make use of their work. It has been and will remain our purpose to effect this epitomization within a single volume by means of greater attention to the practical and clinical aspects of medicine. While not neglecting the more peculiar and theoretic researches, we think that the needs of the active and practising physician are the first and more important to be supplied.

It will be noticed that the plan of pronouncing editorial judgment upon new proposals and investigations has become a more distinctive characteristic of the present volume, and there is a general agreement that it is precisely this feature that will make the book still more acceptable to those whom the demands of practice leave little time to settle matters of controversy

10D18 Coll. of medicine & 1897 Continuation

253039

and doubt, and who must therefore welcome the ripe decisions of those most capable of pronouncing them.

With one unfortunate exception all publishers deserve, and we believe will receive, the gratitude of the profession for the willingness and prompt courtesy with which they helped us with our work. No one journal and no combination of journals can hope to reach the entire profession or to give a complete and digested account of all medical progress. Any proper method, therefore, which aids in bringing the results of medical science to a still larger number of the members of the profession must be looked upon by every earnest physician as worthy of encouragement, helpful of progress, and of benefit to humanity. Any attempt to limit such extension of knowledge is inimical to the profession and to professional progress.

GEORGE M. GOULD.

GENERAL MEDICINE.

By WILLIAM PEPPER, M. D., and ALFRED STENGEL, M. D.,

of Philadelphia.

General Review of the Year's Work.—In the limits of a few introductory sentences we can only note some of the more striking facts and comment upon the tendencies of the investigations of the year under review.

Nothing is more refreshing in the study of a year's medical work than the evidence exhibited in the literature of our own countrymen, as well as in that of foreign nations, that experiment and investigation are taking the place of speculation. The present is undoubtedly an age of experimentation, and those who pursue this method of study reach the most useful results. Already the fruits of laboratory-work are manifest in the greater accuracy of the knowledge of certain affections and in that which is more important to mankind, the discovery of principles that offer a justifiable hope of greater success in prevention and treatment of disease. It is not within our province to refer to diphtheria and its treatment or to comment upon these extensively. Suffice it to say that the same principles that have given to the world a remedy that may at least be assumed of probable value in this disease have been applied to other conditions. We cannot pass the work of Marmorek without particular notice. Whether the serum prepared by this investigator will prove itself as useful in the treatment of erysipelas and other forms of streptococcus-infection as some maintain, or not, time alone can tell. At present the evidence favors a hopeful acceptance of the claims. In small-pox, typhoid fever, tuberculosis, and other infections the results have been far less satisfactory, though flattering reports are not wanting. We have referred to the greater accuracy of knowledge regarding various diseases. This is evidenced in the advance of bacteriology and the titles of reports of cases. Pyocyaneous infection, streptococcemia, infection with the bacillus coli, etc. have taken the place of the more vague and insignificant titles—septicemia, pyemia, etc. Further investigations will doubtless establish more definite distinctions in the symptomatology and nature of the various infections; but for the present it is sufficient that they are beginning to be recognized and separately studied. Certain authors have maintained that acute rheumatism is a form of infection (micrococci), and the evidence is strong and suggestive. Reference may also be made to the positive demonstration of the gonococcus as a cause of general septicemia and of endocardiac and other metastatic lesions. Chemical investigators have been but little less active than the bacteriologists. The problems

of autointoxication and the processes of normal and disordered metabolism are beginning to be understood, and special manifestations are recognized in which specific disturbances of the organic chemistry play an important part. There is the difference between the views of the present day and those of the older authors, that demonstration has taken the place of speculation. We need only refer in this connection to the investigations regarding myxedema and the thyroid gland, to the studies of uric-acid formation, and to the investigations regarding the pathology of gout. Among other evidences of progress, attention may finally be called to the discovery of the specific cause of the bubonic plague by Kitasato, and the method of Elsner for the diagnosis of typhoid fever. These will be discussed more particularly in the appropriate sections.

INFECTIOUS DISEASES.

TYPHOID FEVER.

Essential Identity of Sundry Types.—[The difficulty of establishing an absolute diagnosis of the disease in cases which recover has led to a diversity of opinion regarding the nature of a number of diseases marked by continuous fever, such as "simple continued fever," tropical fever, thermal fever, and the forms described in various localities, such as Malta fever, Mediterranean fever, mountain fever, etc. If the bacteriologic method of Elsner proves as satisfactory as the small number of investigations now at hand would seem to indicate, greater exactness may be expected in the future; for the present, opinion usually takes the place of demonstration, excepting in occasional fatal cases, and these, according to those who maintain the existence of separate febrile diseases resembling typhoid fever, are ascribed to erroneous diagnoses.]

Matas[1] believes that the so-called **continued fevers of Louisiana** are merely mild forms of typhoid fever, basing his opinion upon the fact that they are influenced but little by the cinchona alkaloids, that they occur at all seasons of the year, and in groups apparently the result of infection from a common source. Moreover, in such epidemic cases of typical typhoid fever often develop.

Le Cato[2] identifies the **endemic fever of the Eastern Shore** with typhoid fever. Although malaria is not unknown there, he has never seen a case of typho-malarial fever as described by Woodward, and he is inclined to believe that the two poisons are so specifically distinct as to be in some way mutually antagonistic.

Etiology.—[Nothing of moment has been added to the knowledge of the bacillus of typhoid fever or its life-history.] Freund and Levy[3] record a case of intrauterine transmission of typhoid infection. The woman was attacked with typhoid fever in the fifth month of pregnancy and aborted after the fourth week. Antiseptic precautions were taken during labor, and the authors

[1] New Orl. M. and S. Jour., July, 1895. [2] Va. Med. Monthly, Feb., 1896.
[3] Berl. klin. Woch.

claim that the cervix and external genitalia were rendered practically germ-free. The fetus died immediately after the cord was cut, and 20 minutes later a bacteriologic study of the tissues was begun. Cultures were taken from the spleen, heart's blood, and placenta. A piece of the spleen was placed in nutritive broth and kept in the incubator. Cultures of the typhoid bacillus were obtained, and caused death in mice. The passage of the bacilli into the fetus through the placenta seems, therefore, to have been established. Post-mortem examination of the fetus revealed no lesions. Étienne[1] reports a case of a pregnant woman suffering from typhoid fever. During the course of the disease she aborted, and careful examination of the fetus showed that the spleen was not increased in volume and the intestines presented no lesion, all the organs being, in fact, perfectly healthy. Cultures made from the splenic and hepatic pulp and the blood upon gelatin or agar-agar developed numerous colonies of small short bacilli that gave all the characteristic reactions of the bacillus of Eberth. Stern[2] in a lecture on typhoid fever holds that **the gastric juice** can offer but slight protection in the way of destroying bacilli. Only when there is hyperacidity and hypersecretion is destruction in the stomach likely to occur. Regarding the matter of rendering germs harmless in the intestines, he found that mechanical removal by purgatives or high enemata is the surest method. In 3 of 6 cases he found the bacilli in the blood of the veins or of the spots. Acquired immunity is not due, according to Stern, to the condition of the blood-serum; nevertheless, the serum of persons who have just recovered has a certain protective value, though this varies greatly. High temperatures have no inhibitory action in the growth of the germ.

Samuel Pierson[3] reports **the epidemic** of typhoid fever that occurred in the spring of 1895 **at Stamford, Conn.** From April 15th to May 6th, 253 cases in all were reported. After this the number rapidly decreased, only 135 more cases being reported during the next 3 weeks. The total number of cases reported was 406. Nose-bleed occurred in 117 cases and rash in 360, the latter being in some cases petechial and spread all over the body. Hemorrhage occurred in 73 cases, of whom 12 died. Relapse occurred in only 26 cases; acute nephritis in 9, of which 4 were fatal. Perforation occurred 7 times with 6 deaths and 1 recovery, and phlebitis was seen in several cases. In all there were 27 deaths, being a mortality of 6.6%. No tub-baths were used during the epidemic, but alcohol and iced water sponging, and sometimes rubber-blanket baths, were frequently employed. The source of the epidemic was traced to contaminated milk, and 2 weeks after its sale was stopped there was almost complete cessation of new cases. Schavoir[4] gives a more careful account of the causation of the Stamford epidemic. The large number of children affected suggested that the milk was contaminated, and it was found that the pans in which the milk was kept were washed with

[4] Ibid.

water from what is known as a "dug well;" that is, one walled up with stones, not cemented, and covered with a loose board platform 6 inches above the ground, the well itself being only 13½ feet deep. All the houses in the vicinity were provided with privies. The original cause of the typhoid fever could not be definitely made out, but there seems no doubt it originated in this well; 140 cases occurred in children under 10 years of age, 68 of these being under 5 years of age.

Symptoms.—Atkinson[1] reports an interesting case of typhoid fever, commencing apparently with a paronychia and abscess in the hand, but subsequently marked by high temperature and violent delirium. Typhoid fever was suspected when hemorrhage from the bowels occurred, but there were no rose spots or other of the typical signs of the disease. Death occurred on the 21st day, and at the autopsy the characteristic lesions of typhoid were discovered. [It is to be regretted that no bacteriologic examinations were made of the pus from the palmar abscess. It is very unlikely, however, that this lesion was of particular significance.]

Osler[2] refers to **chills occurring in the course of typhoid fever.** Among 79 cases treated during 1 year, there were 13 in which the disease began with shaking chills. In 2 cases there were several severe rigors, in 3 cases there were 2, while in 8 the rigor was single. Similar rigors occurred in a number of instances at the onset of relapses. A number of cases are recorded in which the chills resulted from treatment. Among these causes were antipyrin, injections of sterilized typhoid bacilli, and external applications of guaiacol. Several cases presented chills at the onset of various complications, and distinctly septic (?) chills occurred during convalescence in severe and protracted cases. One instance is reported in which the patient had suffered with malarial fever for 11 days after convalescence, from which typhoid fever set in with characteristic symptoms, and a chill occurred at the height of the fever. The attack of malaria lasted from Sept. 23d to Oct. 7th; she had frequent chills, and organisms were found in the blood. On Nov. 6th she entered the hospital with all of the symptoms of typhoid fever, but blood examination was negative. On the 7th she had a chill of moderate severity, but not followed by any rise in temperature. The blood was not examined during the chill, but repeated examinations subsequently were always negative. In no instance among 333 cases of malaria and 389 of typhoid fever were the two diseases concurrent. [Reference should here be made to the report of Gilman Thompson; see *Year-Book*, 1896.]

Day[3] describes a case of typhoid fever in which **a rash** somewhat resembling that of typhus fever or the prodromal stage of small-pox occurred. In this instance the eruption was abundant on the chest, abdomen, and back, less marked on the limbs, forehead, and face, but absent on the hands and feet. It consisted of more or less irregular patches, dark red in color, in some places presenting the appearance of groups of ordinary spots, but darker in color.

[1] Va. Med. Monthly, March, 1896. [2] Univ. Med. Mag., Nov., 1895.
[3] Dublin J. of M. Sc., Mar., 1896.

The eruption was raised and soft, and disappeared on pressure. The spots did not correspond to petechiæ, though some left pigmentation after their disappearance. The author states that he has seen at least 10 similar instances. In 4 the subsequent of intestinal hemorrhage was foretold by the occurrence of these eruptions in association with high fever, rapid pulse, distended abdomen, and clear intellect. It is therefore of considerable importance in prognosis.

Stevens[1] reports a case of typhoid fever, with **hemorrhagic nephritis** and uremic symptoms that were relieved by profuse hemorrhage from the bowel. In the course of convalescence a severe attack of rhachialgia occurred.

Zienetz[2] reports a series of cases in which **albuminuria** occurred in cases of typhoid fever. Among 342 cases of this disease, death occurred in 39 and relapses in 11. These cases being excluded, the remaining 292 may be divided into those in which albumin never appeared in the urine, in which group there were 118 cases, and those in which albumin did occur—174 cases. The latter may be divided into cases in which the fever ran its course in 1, 2, 3 weeks, or more. Of the cases terminating in 2 weeks, 31 showed albuminuria, 23 no albumin. Of the cases of 3 weeks' duration, albumin was absent in 37 and present in 57. Of the cases lasting 4 weeks, albumin was wanting in 29 and present in 51. Of the cases of 5 weeks' duration, albumin was wanting in 15 and occurred in 27. Of those lasting 6 weeks, there were only 2 without albumin and 12 with albuminuria. In the group of cases of 7 weeks' duration, albumin was present in 3 and absent in 3. In 1 case lasting 8 weeks albumin was absent. Among the 11 cases in which relapses occurred there was albuminuria in 5, and among the 37 fatal cases it was present in 35. The author does not believe that the diet plays as conspicuous a part in the occurrence of albuminuria in typhoid as certain authors have held. [It has seemed to us that the frequency of albuminuria in the cases of typhoid fever under our care in the last two years has been much greater than formerly, though we have made no extended analyses. Several cases have been of the type in which the renal manifestations were striking from the first, and in which blood-casts and free blood are found in the urine. This may, of course, be coincidental, but the suggestion has repeatedly occurred to us that the prevalence of influenza in recent years is of some importance in this connection.]

Delvic[3] considers **ulceration in the mouth** quite common in typhoid fever. It affects the anterior pillars of the pharynx most frequently, but the sides of the tongue and anterior surface of the soft palate and the tip of the tongue may be affected. The ulceration is always superficial, oval or round, and the edges regular and not undermined. As a rule, there are no symptoms, the ulcerations being indolent and only found when looked for. The author agrees with Tripier that these ulcers run a parallel course with the intestinal lesions, and he regards them as important in furnishing an accessible guide to

[1] Univ. Med. Mag., May, 1896. [2] Wien. med. Woch., Jan. 1, 1896.
[3] Prov. méd., No. 50–51, 1895.

the condition of the intestines. The progress of the case may be judged and the relapses may be predicted by the observations of these ulcers. He finds them in about one-sixth of the cases. [One of the editors is able to confirm this observation to a certain extent, having found erosions corresponding more or less accurately with the descriptions given above in a number of cases of typhoid fever. The lesions, however, have been extremely superficial, and in no sense characteristic of the disease. Other febrile disorders presented the same peculiarity.]

Osler [1] has observed extreme **tenderness of the toes** in 3 cases of typhoid fever, and believes that it should be classified as a neuritis.

Sweet [2] reports 31 cases of typhoid fever that were observed in the Napier Hospital during the past year. The majority of these occurred during the months of February, March, and April, but cases were present during the whole year. The average duration of the disease during the period under observation was 13½ days, the maximum period being 55 days. In 22 cases deep rose-colored spots were observed, and in about two-thirds of these there were repeated eruptions. Violent delirium occurred in 2 cases and muttering delirium in 5. Hemorrhages occurred in 4 cases, 2 of them having repeated attacks; relapses occurred in 2; in 4 cases there was thrombosis of one femoral vein; in 2 cases severe subcutaneous abscess occurred. There were no deaths. The treatment employed was chlorin or sulphurous acid. The most severe case occurred in a girl of 16, in whom the temperature remained above normal for 55 days with a maximum of 104.2°. She had repeated hemorrhages from the bowel, and diarrhea persisted for 6 weeks after the temperature reached normal. Emaciation was extreme and convalescence very slow.

Morse [3] has studied the **cases** of typhoid fever occurring in children under 15 during 13 years **in the Boston City Hospital.** The total number was 284, being 7.07% of all the cases treated during that time. He concludes that it is a common disease in children, though rare below the age of 2. The mortality in the cases under 15 is about 6%, but increases directly with the age. The course is shorter and less severe than in adults, but the onset is acute in about one-third of the cases in the first 5 years of life, and in one-fifth of the cases in the next 5 years. In general the clinical history is practically the same as in adults, but crying at night and meningeal symptoms are common, and marked nervous symptoms of some kind occurred in at least 25%.

Musser [4] reports a case of typhoid fever in which the **temperature** did not reach normal until 73 days had elapsed. There was no complication of any kind.

Complications and Sequels.—Creagh [5] reports an interesting case of typhoid fever in a non-phthisical patient in which hemoptysis occurred as a

[1] Johns Hopkins Hosp. Rep., v., Nos. 6, 9, 1895.
[2] New Zealand Med. Jour., Dunedin, Jan., 1896.
[3] Bost. Med. and Surg. Jour., Feb. 27, 1896.
[4] Univ. Med. Mag., Nov., 1895.
[5] Lancet, Lond., Nov. 30, 1895.

complication, and proved fatal on its recurrence. The patient, a man of 35, had been well with the exception of an attack of what was regarded as rheumatic fever some time previously. The first attack of hemoptysis occurred on the 16th day of the disease, no evidence of cardiac or of a serious pulmonary disease having existed. There were, however, signs of rather marked bronchitis. The patient died on the 17th day. Considerable cyanosis was noted. The patient's history gave no evidence of phthisis or hemophilia. The author remarks that he has been unable to find records of hemoptysis as a complication of typhoid fever in the text-books. [Cases of this character occur occasionally, and may be of different sorts. Unfortunately, no autopsy was made. We have ourselves seen a case in which serious hemoptysis occurred in a patient suffering with typhoid fever, and in which the autopsy showed the cause to be pulmonary thrombosis. Such an explanation might be applicable to the present case. It is also to be remembered that a marked hemorrhagic tendency may be developed in typhoid fever, and hemoptysis may be the expression of this diathesis. Thus in one of our cases death occurred from uncontrollable epistaxis and hematemesis in the second week.]

Lannois[1] observed a case of **abscess of the liver** following typhoid fever in which the pus of the abscess contained the bacillus of typhoid. He divides abscesses of the liver following this disease into those due to metastasis, those due to typhoid ulceration of the biliary passages, and those due to pylephlebitis. His own case belonged to the last group, and occurred in a patient who had been afebrile 3 days at the end of the attack of typhoid fever. He was then taken with renewed fever, followed by swelling of the abdomen, pain in the right side, and the signs of pleurisy at both bases. Three days after this the patient died, and partly healed ulcers were found within the ileum. Adherent clots were found in the portal, the inferior mesenteric, and the splenic veins, and in the liver were seen a number of abscesses. From the pus of the latter several varieties of organisms were obtained, and one of these closely resembled that of typhoid fever, though it differed slightly in some of its cultural properties.

Pansini[2] reports a case of **thrombosis of the iliac veins** and of the lower part of the ascending cava following typhoid fever, with peritonitis; edema, lividity, pain, and loss of power were among the significant symptoms. The author refers to the statistical article of Vimont, who was able to collect 112 cases from literature up to the year 1890. The diagnosis of the seat of the thrombosis is aided by the knowledge of the collateral circulation. The venous systems of the superior and inferior cavæ are united by anastomoses of the superior diaphragmatic veins with the inferior by the vertebral veins, both anterior and posterior; the greater and lesser azygos veins and the intercostal, lumbar, and sacral veins belonging to the anterior plexus; by the veins of the abdominal walls, the epigastric vein, and external pudendal below, and the external mammary and intercostal veins above; finally, by certain branches of the portal veins, those which become enlarged in cirrhosis of the liver.

[1] Rev. de Méd., Nov., 1895.

[2] Centralbl. f. innere Med., June 6, 1896.

Quervain[1] describes a case of **gangrene** following typhoid fever. The author quotes the literature, showing that this condition is one of great rarity. His own case occurred in a man aged 25, previously healthy, who had an attack of typhoid fever of moderate severity. Severe pain in the right leg, followed by pallor of the feet and lower limbs and diminished sensibility and coldness, occurred. The pain became intense and the pulse and temperature increased. Slight edema and great pain in the popliteal space followed. Later loss of motion and sensation, then cyanosis and gangrene, occurred. Amputation above the knee was performed. Slight phlebitis occurred in the left leg, and examination of the amputated limb showed a rather firm thrombus in the popliteal artery and many of its branches.

Parsons[2] reports 6 cases in which **bone-lesions** were found after typhoid fever. These lesions appear from 1 to 16 months after the fever, and the author finds but 1 case in literature in which it occurred during the fever. The tibia is most frequently involved, while the hands and feet are especially free. The ribs and costal cartilages are frequently involved. The symptoms are pain, usually localized to the seat of subsequent necrosis and resembling syphilis; subsequently swelling and perhaps necrosis, though resolution without necrosis may occur. In 5 of the cases bacteriologic examination was made, and typhoid bacilli were found in pure cultures 4 times, and associated with staphylococcus pyogenes citreus in the 4th case.

Tuffier and Widal[3] report 2 cases of typhoid fever in which, one month after convalescence, various **tumors** occurred **in** connection with **the long bones** and were found to contain pus. In both cases the pus was sterile, although careful cultures were made on various media.

Himmelsbach[4] has observed 3 cases of typhoid fever **complicating pregnancy** at periods of from the 3d to the 5th month. Each of these was treated with cold baths, and all at the onset presented a grave type of fever, but responded quickly to the baths without interference with the pregnant state.

Simpson[5] records a case of typhoid fever followed by unusual **nervous sequelæ.** The patient, a woman of 45, was healthy until she was 28, when she contracted typhoid fever. During the convalescence she became suddenly unconscious without warning, the limbs became rigid, and the face pale. There was no clonic period to the attacks, which were repeated as often as five times daily. After the seizure she was dazed, and during the attack she sometimes bit the tongue and had involuntary micturition. She was confined to bed for 9 years, at the end of which time there was gradual improvement, though she had regular attacks on Sunday (the day on which the first fit occurred) and was sometimes confined to bed. Attacks of vomiting were sometimes severe, and the patient's mental condition was undoubtedly affected.

Diagnosis.—[We have already taken occasion to remark upon the neces-

[1] Centralbl. f. innere Med., No. 33, 1895.

[5] Edinb. Med. Jour., Jan., 1896.

sity of greater accuracy in the methods of diagnosis at the present time. In typical cases running a typical course the practitioner finds little difficulty, but in atypical, irregular, or abortive cases, and in some of the febrile affections variously regarded as typhoid fever or as independent affections, the need of more accurate means of diagnosis is keenly felt by the most experienced clinicians. Unfortunately, the bacteriologist has hitherto given little aid, and the chemical examinations of the urine and other clinical methods have been unavailing in doubtful cases. The hematologist has aided somewhat in determining the absence of leucocytosis, but the same occurs in other febrile diseases. The method of Elsner, alluded to in the following abstracts, seems to hold out greater hope of value than any of the bacteriologic procedures thus far suggested. Nothing, however, can be concluded from the small number of cases at hand. Time and further investigations will show how far this method is reliable; at the present we can only look upon it as hopeful.]

Lazarus[1] has investigated the merits of **Elsner's method** of diagnosis of typhoid fever. This method consists in the preparation of cultures from water, food, or soil, or from the stools of patients suffering from typhoid fever, upon a special culture-medium. The latter is composed of Holz's acid potato-gelatin with 1% of potassium iodid. Upon this medium only a few forms of bacteria will grow, and among these the bacterium coli and the typhoid bacillus. The investigations of Elsner showed that the bacillus of typhoid fever may be readily distinguished from the bacillus coli by his method. In contradistinction from the last-named form, the colonies of typhoid bacilli are slow in growth and scarcely visible under low powers for 24 hours, whereas the coli colonies show a considerable growth at this period. After 48 hours the typhoid cultures present themselves as small glistening aggregations having the appearance of drops of water with finely moulded structure. The coli colonies are larger, much more granular, and brownish in color. Only in cases in which the plates are richly covered with colonies, and in which the number of colonies prevents active growth, do the coli colonies resemble those of typhoid. On the plates prepared so as to reduce the number of colonies mistakes of diagnosis can scarcely occur. Elsner[2] found in 17 cases of typhoid fever that pure cultures of typhoid bacilli could be obtained in 15. The 2 negative cases are unimportant, as 1 of these was not examined until the 7th week, and the other only 2 days before complete defervescence. The present author (Lazarus) has studied 5 cases of typhoid fever in the active stage and 16 in various stages of convalescence. Among the 5 cases of the first group typhoid colonies were obtained without difficulty in a number of trials. In many cases the diagnosis was made in 48 hours; in only 1 case the characteristic colonies were not obtained until the 3d day. In convalescent cases among those which had been without fever from 3 to 6 days, only 3 showed typhoid bacilli in the stools after repeated examinations. In no instance in which the stools of other cases were examined could colonies of the same kind be de-

[1] Berl. klin. Woch., Dec. 9, 1895. [2] Zeit. f. Hyg. u. Infectionskrankh., Bd. xxii.

tected. Chantemesse[1] advocates Elsner's method of examining the stools for typhoid bacilli for the early diagnosis of the disease, and reports cases. At first 3 were examined, once each, with negative results, but there were errors of technique. Subsequently 13 cases were examined with positive results. By this means the diagnosis was made at the 7th day in 8 cases; at the 8th, 12th, and 13th day in 1 case each; at the 17th day in 2 cases; at the 20th day in 3 cases; and at the 19th, 21st, 23d, and 26th days in 1 case each. In 3 of the cases the diagnosis would otherwise have been doubtful.

Walthalet[2] made repeated examinations of stools in 12 cases of typhoid fever, and was able in a small number of his trials to develop cultures of the typhoid bacilli. As a rule, the bacillus coli grew with such rapidity that the specific form was not discovered. It is evident that the ordinary bacteriologic examination of the stools can serve but little purpose for diagnosis.

Semple[3] examined **the urine** of 7 cases of typhoid fever bacteriologically, and was able to demonstrate the specific bacilli in 6. He therefore urges careful disinfection of the urine in every case.

Prognosis.—Day[4] refers to a peculiar **dark-red rash** resembling that of typhus fever or of the prodromal stage of smallpox as an indication of prognostic value in typhoid fever. In 4 cases this rash with rapid pulse, high fever, distended abdomen, and clear intellect presaged intestinal hemorrhage.

[A number of **statistical articles** have appeared during the year, and deductions regarding the value of treatment, the prognosis under varying conditions, etc. have been made. Undoubtedly, the number of cases upon which such conclusions are usually based does not warrant positive deductions. Nothing is more certain than the fallacy of statistics, and discriminating readers will always look askance at extravagant claims based upon such evidence. On the other hand, the experience of careful and conservative observers must always have a certain measure of authority, even beyond the limits that the absolute rule of chance would warrant. Personal judgments of known authorities are always important.] Prince[5] points out that a considerable number of cases are necessary to render statistics regarding typhoid fever reliable. It would appear from his figures that the element of chance can only be eliminated when the number of cases is from 800 to 1000, and an equal number of cases is required to obtain a standard of mortality of different forms of treatment. [Other writers, as Wieland, have given even larger figures than the above, but we need not enter upon the discussion in greater detail at the present time. The following article may, however, be referred to in the same connection.] Simon[6] gives statistics to prove that typhoid fever is now more benign, or at least that the death-rate is diminishing, and that therefore statistics of various methods of treatment are apt to be fallacious.

Treatment.—[The **Brand method** of cold bathing has been attacked with much vigor by a number of writers in the last year or two. Some of

[1] Compt. rend. de la Soc. de Biol., Mar. 6, 1896.
[2] Ann. de l'Inst. Pasteur, No. 4, 1895.
[3] Lancet, Lond., July 27, 1895.
[4] Dublin J. M. Sc., Mar., 1896.
[5] Bost. Med. and Surg. Jour., Oct. 17, 1895.
[6] Birmingh. M. Rev., May, 1896.

these have urged other methods; some advocate expectant measures; some have not hesitated to put forward plans of treatment as capable of aborting the disease. It is noteworthy that the experience of those who have recorded the results of treatment in large hospitals has with great uniformity been favorable to the Brand method. Collected cases gathered from all possible sources in support of some special form of treatment, and for the most part inadequately reported, do not compare in reliability with the other kind of evidence. Our own experience is wholly on the side of those who maintain the value of cold bathing; and, though we agree with Osler and other conservative advocates of the method that it is unnecessary or perhaps inadvisable to insist in every case upon this plan of treatment, there is no doubt in our mind that the mortality has been greatly reduced wherever the treatment has been properly carried out. This has been true of our own experience, and in addition the cases have been strikingly less severe and troublesome since we have adopted the treatment. Untoward results undoubtedly occur, but it is no more necessary to exercise judgment in the use of the Brand method than in carrying out any other form of treatment. The element of judgment cannot of course be neglected.] Osler[1] reports the statistics of **Johns Hopkins Hospital** in typhoid fever. During the six years ending May 15, 1895, 389 cases were admitted, 34 died, giving a mortality of 24.2%. Of these, 33 were treated medically, with 8 deaths; 299 cases were treated by the baths, of whom 20 died, a mortality of 6.67%. Of the remaining cases, the majority were admitted late with falling temperatures, some never developed very high fever, and a third group presented serious complications, such as hemorrhages or perforation. Of these 57 cases not bathed, 6 died. He concludes that the cold-bath treatment rigidly enforced appears to save 6 to 8 in each 100 typhoid patients. Osler himself is inclined "to pray for a method which may be, while equally life-saving, to put it mildly, less disagreeable."

J. C. Wilson[2] reports upon his experience at the Pennsylvania Hospital with systematic cold bathing in the treatment of typhoid fever. Among 71 cases under his care, the Brand method was used in all but 5, and the number of deaths was 4, or a mortality of 6.3% in the 63 cases (8 being still in the wards, and therefore excluded). Of the cases that recovered, 3 were not bathed, and of the fatal cases, 2 were not treated in this way. Deducting these 5 cases, there were 2 deaths in 58 cases, a mortality of 3.4%. The author points out that a series as small as this one does not justify positive conclusions. In his experience at the German Hospital the mortality varied in different groups; thus there were 40 cases without a death, then 54 with 1 death, 66 with 7 deaths, 66 with 4 deaths, 74 with 8 deaths, and, finally, 108 with 12 deaths. Among the 71 cases of the present series relapses occurred in 5, and all of these recovered. Perforation occurred in 3 cases, but the conditions prevented surgical interference. The average stay in the hospital of the cases which recovered was 35.5 days. Five of the cases were of short duration, the history indicating an illness of less than a week before

[1] Med. News, Oct. 12, 1896.

[2] Ibid., Nov. 30, 1895.

admission, and defervescence being complete in 5 to 7 days. Benedict[1] makes a violent attack upon the Brand method of treatment. He claims that bathing produces a depression which is something more than the mere abstraction of heat-units, and that it is fair to doubt the good faith of those who practise immersion in hospitals, but do not urge it on their private patients. [He offers no other valid arguments.] Baruch,[2] in reply to Benedict's article criticising the Brand treatment, quotes statistics involving many thousand cases, which show that the mortality has on the average been reduced from about 20 to about 7% by this method. Patek[3] also makes a vigorous reply to Benedict's criticism of the Brand treatment, denying, in the first place, the depressing effects of bathing, and, in the second, the production of internal congestion.

Simon[4] discusses **the treatment** of typhoid fever at great length. He concludes that it should be essentially rational, and that we have no specific remedial agent. He prefers turpentine to the other intestinal antiseptics that have been suggested. Of 304 cases in his own service with 51 deaths, 22 were apparently due to toxemia and 29 to other causes. Even supposing that the Brand method could have prevented some of the deaths of the former group, he urges that we must still have better proof of its benefits before it could be universally adopted.

Hotchkiss[5] reports a case of typhoid fever with **intestinal perforation** in which **surgical operation** was undertaken. Incision in the middle line was made and a large amount of serous liquid was removed; the perforation was found 5 inches above the valve, and the area around this was turned in longitudinally more than an inch and sutured. A hot salt solution was used to flush out the abdominal cavity. The patient died after four hours. The author points out that of 17 cases reported 3 only have been successful. Nevertheless, the operation is justified and offers some hope.

[The attempts to apply the methods of **serum therapeutics** to this disease have thus far met with little encouragement. The following investigations, however, are sufficiently interesting to deserve further prosecution.]

Chantemesse[6] in his paper on the value of Elsner's method of diagnosis refers to his experience with serum injections. These cases were injected with serum from a horse that had been rendered immune to the typhoid bacillus, and in all a steady fall of temperature occurred such as takes place in abortive typhoid. Klemperer and Levy[7] contribute experiments to show the possibility of rendering animals immune from typhoid infection, or of curing the disease when infection has already occurred, by injection of serum of immunized dogs. The serum was used in 5 patients, each in the first week. The subsequent course of the disease showed no striking results, but all of the cases went on to convalescence as mild typhoid fever. They believe the serum may have

[7] Berl. klin. Woch., July 15, 1895.

had the effect of making the disease milder and shorter than would have been the case, but do not make positive assertions.

Henshaw[1] has prepared a bouillon with **calves' thymus** which he has inoculated with typhoid bacilli. This he sterilized at 63° C., and then injected it into cases of typhoid fever. The initial dose is 1 to 2 c.cm., increasing up to 5. He reports in all 13 cases, in which the results in 8 were as satisfactory as could be desired; in 4 no effect was noticed, and there was 1 death from hemorrhage. In connection with other cases recorded in literature he is able to report a total of 98 cases of typhoid fever treated by this method, and, when the treatment has been started reasonably early, there has not been a single death as yet recorded. He believes it is desirable to use a more concentrated and stronger culture.

Clemow[2] reported before the Clinical Society of London a case of typhoid fever in which a severe rigor, followed by a temperature of 106.7° and delirium, occurred on the 14th day. Ice-sponging failed to control the fever and other symptoms; the patient became deeply cyanosed, and was apparently *in articulo mortis* when **venesection** was performed, 8 oz. of blood being removed. Improvement began at once, and eventually the patient recovered.

Abortive Treatment.—A number of such methods are suggested. That of Woodbridge has attracted more attention in this country, but others are offered with the same flattering statistical evidence. Woodbridge[3] contributes elaborate papers upon his abortive treatment of typhoid fever, which consists in the administration of podophyllum, calomel, guaiacol, eucalyptol, and menthol according to certain definite formulæ. The number of instances reported to him by different physicians are included to illustrate the possibility of aborting this disease by the method of treatment recommended by the author. None of these cases seem to have been studied in hospital practice.

Shields[4] reports 28 cases of typhoid treated by **the Woodbridge method,** with 1 death, a patient who had persisted in eating solid food. In addition to the regular method, he employed sponge baths and rectal injections of boiled water and carbolic acid. The average duration of 23 of the cases was $15\frac{1}{2}$ days. The other cases did not appear to benefit by the treatment. He concludes that the results have not been as good as is claimed by Dr. Woodbridge, but that the remedies have a markedly beneficial effect upon tympanites, relieving it in a few days. He believes that lavage of the stomach and rectal injections are of great assistance. In a case benefited by the Woodbridge treatment aggravation occurred when it was intermitted. Schoenfeld[5] reports 5 severe cases of typhoid fever treated by the Woodbridge method without a death, and with results that he does not believe possible by any other method. Orton[6] reports 8 cases of typhoid fever treated by Woodbridge's method with no deaths. In 12 cases treated by other methods there were 3 deaths. Quine[7]

[7] Ibid., May 23, 1896.

reports 21 consecutive recoveries under a modified Woodbridge treatment, but he warns against too great reliance on statistics, on the ground that the disease has been growing more mild of late. Duffield[1] reports 16 cases of typhoid fever; of these 3 were treated by bathing and antipyretics. The average duration of the fever was 6.1 days, the maximum period of duration being 9.6 days; 13 cases were treated exclusively by the Woodbridge method. The average duration of fever in these cases was $13\frac{7}{8}$ days. Sponge baths, however, were also employed whenever the temperature reached 103°. No examinations for bacilli were made, and clinical histories are not given. In 1 case the temperature reached normal on the 5th day of treatment, and the patient is said to have been sick for 3 or 4 days before admission. A serious case occurring during the puerperium received, in addition to the Woodbridge treatment, plunge baths, sponge baths, and cold packs. Two cases are reported as having been aborted, 1 on the 7th day and 1 on the 13th day. All the cases but 1 are said to have had rose spots. [The above reports indicate the claims made for various plans of treatment from time to time. We may refer to the following criticism of Osler as indicating the conservative view of the value of most methods. A greater minuteness of attention to diagnosis might frequently be desirable in the reports of brilliant results.]

Osler[2] in an address upon **the fevers of the South** takes occasion to say that the advocates of the abortive and antiseptic treatment of typhoid fever must bring forward a much stronger body of evidence than has been presented, and in a much more rational way, before they can hope to carry conviction to the skeptic. He agrees with Woodward in his contention that typhoid fever may coexist with malarial infection, and goes on to discuss a certain peculiar continued fever that occurs in the South, and that is apparently neither typhoid nor malaria, but appears to be a disease of itself. [Other methods of treatment seem to enjoy the reputation urged for the Woodbridge plan, as the following references sufficiently indicate.]

Bignami[3] claims to have obtained excellent results from the treatment of typhoid fever by **phenacetin.** Among 200 cases in private, only 6 died, and in these cases disobedience or poor surroundings affected the result. He gives from 1 to 3 gr. every 4 hours at first, later $7\frac{1}{2}$ gr. regularly every 6 hours.

Thistle[4] believes that the proper treatment of typhoid fever is by **catharsis,** preference being given to calomel in $\frac{1}{2}$ gr. doses frequently repeated. He reports 172 cases with a mortality of 5. In no case did death occur either from toxemia or from perforation.

Wilcox[5] advocates the use of **chlorin-water** in the treatment of typhoid fever, holding that this remedy may be safely administered until complete disinfection of the alimentary canal is obtained. Under its use he finds improvement in the gastrointestinal conditions, in the general strength and nervous

symptoms, and a shortening of the duration of the disease. The author includes 4 case-histories. [The number of cases recorded does not permit expression of positive opinion, and as the author states that he does not employ the remedy until ulceration has been established and systemic infection has become marked, it would seem difficult to assert that it has power to shorten the duration of the disease. Regarding his statement that it secures complete intestinal antisepsis, we need only allude to the uniformly contrary results obtained by all experimenters who have studied this question. No systematic studies of the urine or stools were made in this case to determine positively that antisepsis was secured, his opinion being based apparently entirely upon the loss of odor of the stools.]

TUBERCULOSIS.

[Little has been added to previous knowledge of this disease by the contributions of the past year. A number of communications upon the treatment have been published, and some of these contain flattering statistics. Upon the whole, however, there is little sure evidence of progress. Serum-therapy has been lauded and certain preparations have been extensively used. The evidence, however, justifies no deductions. More laboratory and less clinical work in this direction are desirable.]

Etiology.—Bowditch [1] urges that too great terror has been excited by the efforts of the profession to convince the laity of the contagiousness of tuberculosis. He maintains that the only source of infection is the sputum, and that when this is properly destroyed even hospitals for consumptives are not sources of danger to a community, but, on the contrary, really a protection. Heffron [2] suggests compulsory registration of every case of tuberculosis and the prevention of contamination by expectoration in public places. Vaughan [3] takes a similar position, and advocates the prevention of the sale of **meat and milk from tuberculous animals** and the disinfection of the sputum and other excretions from the diseased human body.

Wells [4] claims that a careful study of the **statistics** shows that pulmonary tuberculosis has decreased in prevalence during the past, and that the tendency is toward still further reduction, although in the case of the United States there is apparently an increase at present.

Cornet [5] in a contribution on the **prophylaxis** of tuberculosis points out that the disease is growing decidedly less frequent in Prussia than formerly, and concludes that in that state, during the period of 1887 to 1893, 70,000 less persons died of tuberculosis than would have been expected from the mortality tables established by earlier experience. Hinsdale,[6] on the contrary, shows that the **death-rate** from tuberculosis in the city of Philadelphia has gradually diminished since 1880, there being 342 from this cause to 100,000 of population in 1870; 317 in 1880; 264 in 1890; 220 in 1894. The same

[3] Ibid., Mar. 7, 1896.
[4] Jour. Am. Med. Assoc., Feb. 8, 1896.
[5] Berl. klin. Woch., No. 20, 1895.
[6] Med. News, Aug. 24, 1895.

decrease has also taken place in New York. Bollinger[1] contributes an interesting study of the mortality of pulmonary tuberculosis in various parts of Germany, and finds that there is a decided decrease, especially in the large cities (Vienna, Berlin, Hamburg, and Munich). He was able to establish this fact, not only from statistical evidence, but also in the postmortem room, and he admits the improved state is due to better sanitation as well as to prophylaxis.

Audvord[2] has studied the distribution of **tuberculosis in Norway.** He finds that below the age of 15 years but one-third of the cases of tuberculosis were pulmonary. In this period occurred nearly all the cases of tubercular meningitis and more than one-half of tuberculous scrofula. There did not seem to be any particular indication that tuberculosis was more common in the city than in the country, the figures for the different districts and different cities being very variable. Meteorologic conditions, however, played a more important part, sudden and irregular variations of the temperature and high winds being particularly favorable to the prevalence of tubercular conditions.

Otis[3] believes that the best means of protecting the nontuberculous members of a community is by providing **special hospitals** for patients suffering from phthisis, and that the patients themselves have much greater chances of recovery in such institutions. He quotes various statistics to show that such hospitals are rarely sources of contagion, urging particularly the small mortality among the attendants. A further advantage consists in the opportunity for more careful and thorough study of tuberculosis, both clinically and pathologically. He particularly deplores the attempt to attract patients to certain of these hospitals by specious claims of specific methods of treatment.

Hance[4] has repeated Cornet's experiments, collecting **the dust from the floors and walls** of the various buildings at the sanatorium for consumptives, suspending it in sterilized water, and inoculating a number of guinea-pigs. Of 81 animals used, 5 developed tuberculosis, being half of the number injected with the dust from a cottage in which a patient had been reported for carelessness. Four of the pigs died of various infectious diseases, and the remainder were healthy. He concludes that it is perfectly possible to avoid all danger of contagion. Jaccoud[5] reports 3 exceedingly interesting cases that were admitted to his service suffering from recent accidents. All 3 patients, although apparently perfectly healthy at the time of admission, subsequently developed tuberculosis. He discusses at length the question of infection at the hospital, and concludes that, although it cannot be positively asserted, it is not improbable. He believes, however, that it is important to protect hospital patients against the bacillus, which may be accomplished by careful hygienic regulations and the abolition of dust. In the discussion that followed, Nochard reported 2 cases from his veterinary experience in which tuberculosis, arising from exposure in an infected stall, seemed certain. Péan

[1] Schwindsuchtsterblickheit, etc., München, J. T. Lehmann, 1895.

[5] Revue de la l'Acad. de Méd., Jan., 1896.

reported 3 cases from his service in which tubercular infection occurred in wounds that had been received accidentally. Dumont Pallier spoke upon the other side, and doubted if the death-rate of tuberculosis was lower in those wards where precautions were taken than in those in which they were neglected.

Kempner[1] has studied the question of tuberculosis **in young infants** under the guidance of Bollinger, and concludes that only in exceptional instances is the tuberculosis of infants a congenital infection; in the majority of cases it is due to postfetal infection.

Bar and Renon[2] have collected **placental blood** in 5 cases from tubercular women, and inoculated guinea-pigs with it, in 2 cases with positive results; in 3 with negative. Of the positive cases, 1 child was born dead, and another died of pneumonia shortly after birth.

Solly[3] contributes a paper on the influence of **heredity** on phthisis, basing his remarks on 250 cases. Among these there was a family history in 139 (parental, 72; grandparental, 19; collateral, 48) and 111 acquired cases. Regarding sex, 72.8% were males and 27.2% females, 52.7% of the males and 65% of the females exhibiting a family tendency. The author holds that a connection between phthisis in an individual and phthisis in the family may be exercised in one of three ways—viz. by inheritance of bacilli, by inheritance of susceptibility, or by contagion.

Holladay[4] reports an **epidemic of acute phthisis** that occurred in a narrow valley in Virginia. In all the patients there was a possibility of contagion, 3 of the patients being sisters and living in the same house. Of the 7 cases, 3 made complete recoveries, 1 a temporary recovery, and 3 died.

Symptoms.—Maragliano[5] holds that tuberculosis may occur in a permanently latent form—that is, without ever becoming active. On the other hand, the disease may be latent for a time and then be followed by active manifestations, or may be intermittently latent. In the last group he includes cases of recurrent bronchitis in apparently nontuberculous persons. **Masked tuberculosis** may be of two forms—one accompanied by fever, sometimes of considerable degree, and sometimes attended by gastrointestinal symptoms and other appearances of typhoid fever; the second form, unattended by fever, but of dystrophic type, characterized especially by general malaise, wasting, etc. In the first group he includes the so-called "growth-fever" of young adolescents. He believes the febrile group of cases to be due to the action of the proteids of the bacilli, while the dystrophic symptoms are due to toxins. In the diagnosis he relies upon the evidence obtained by injecting tuberculin, stating that among 32 persons apparently in good health a reaction was obtained in 9%, while among 47 subjects who gave a tuberculous family history, and who had themselves suffered with repeated bronchitis, a reaction occurred in 23%. The mere occurrence of fever after the injection does not seem to be

[5] Gazz. degli Osped., April 18, 1896.

sufficient to indicate tuberculosis; there should be in addition some local lesions of a suspicious character. If, however, definite reactive signs are found with doses below 10 mg., he would admit the presence of tuberculosis.

Leith [1] reports a case of a man 53 years of age with tubercular family history, slight cough, and scanty expectoration. His sputum presented the appearance of an almost pure artificial culture of the tubercle bacilli. Under climatic and other treatment he gained greatly in strength and weight and the bacilli apparently steadily diminished in numbers. After 4 years his condition was as good as upon the first visit. Leith regards the case as one of **incipient phthisis**—that is, a disease localized in one apex without physical signs.

Whitelaw [2] has been struck by the fact that **hemorrhage of the lungs** frequently occurred among his patients when "colliery warnings" were published. This led to his investigation of the barometric pressure and its relations to hemorrhages. Not only pulmonary hemorrhages, but also bleeding from other parts, seem to occur with especial frequency when the pressure is above the ordinary; 15 cases are alluded to in evidence of this view.

Lanz [3] has studied the amount of **nitrogen excreted in the sputum** in cases of pulmonary tuberculosis, in a case of pyopneumothorax, in a case of pulmonary gangrene, and one of croupous pneumonia. He finds that although the loss in a single day may be comparatively insignificant, nevertheless in the course of time in a protracted disease a very considerable amount of albumin may be lost; and it is of more significance when it is considered that the organism is already depressed as the result of the diseased process.

Moraczewski [4] reports the case of a patient suffering with pulmonary and peritoneal tuberculosis in which the urine was extremely dark-colored. There was no methemoglobin, but much indican. The urine gave off the reactions for alkapton, becoming deeply brown or dark-colored when alkalies were added. The latter color developed especially when exposed to air; it did not occur when air was excluded. **Alkaptonuria** is usually a chronic disease, but in this case it developed suddenly. The author believes its presence due to decomposition of albumin.

Barie [5] contributes an elaborate article on **pulmonary tuberculosis of the aged.** The statistics cited from the literature and his own statistics show that the disease is quite frequently developed in aged persons. Thus in the reports for 10 years of six of the large hospitals he found 2202 deaths from tuberculosis of the lung in persons above 60 years among a total number of deaths of 92,141. The mortality was therefore 2293 of the total number. Of these instances, 1604 were males and 598 females. The pathologic anatomy distinguishes itself in some particulars from that of phthisis in younger individuals. The chronic cases are in particular characterized by a tendency to bronchitis and emphysema and to fibroid change. Referring to the occurrence of tuberculosis and cancer, the author remarks that the view of

Rokitansky must be abandoned—that indeed cancer, particularly that affecting the esophagus or other parts of the gastrointestinal tract, seems to predispose to tuberculosis. The clinical features differ in some particulars from those in young persons. Cough and expectoration are especially apt to be wanting; hemoptysis, however, is not, in his experience, as rare as some writers have maintained. Digestive disturbances and diarrhea are frequent, while dyspnea and night-sweats are less pronounced. The clinical classification pursued in his detailed study is the following:

A. Chronic forms: 1. Bronchitic or catarrhal; 2. Latent, in which signs may be wanting to the end; 3. Chronic ulcerated form, in which signs are present; 4. Fibro-emphysematous form or fibroid phthisis; 5. Hemoptysic form; 6. Pleuritic.

B. Acute and subacute forms: 1. Latent; 2. Pyrexial, including (*a*) granular (miliary) tuberculosis of the pneumonic type, and (*b*) of the typhoid type; 3. Galloping consumption of the aged.

[Repeatedly in our experience in the wards of the Philadelphia Hospital we have seen cases of acute pulmonary tuberculosis in the aged, and very recently two striking cases have been under our observation. In a number of these instances the disease has been quite acute and of decidedly pneumonic type. The evidences of general toxemia have been at times very marked.]

David[1] contributes a study of the **pretuberculous polyuria** described by Robin. This form of disease is usually seen in young men of nervous temperament. It comes on abruptly with fever, weakness, and pains in the loins, and a few days later, when these symptoms subside, polyuria occurs. The thirst is increased, the appetite diminishes, and moderate fever continues. Signs of tuberculosis may appear at the same time or may not be developed until later. The polyuria gradually diminishes, and the phthisis which follows is generally chronic in its course. David believes the polyuria serves to eliminate poisons from the system, and he therefore thinks it should not be checked.

Teissier[2] records a case of **pretuberculous albuminuria,** and points out that this condition occurs in young persons as a premonitory stage of phthisis. Its origin is difficult to explain, but he believes it due to the congestive action of the tuberculous virus upon the renal structure. He cites that Bouchard has shown that tuberculin exerts a dilating influence on the blood-vessels, and Guinard and Bory have obtained transient albuminuria. He believes this pretuberculous albuminuria is due to intoxication with tuberculin before systemic infection has become marked. It is somewhat cyclic, and is characterized by the presence of albumin in pale urine of high specific gravity and very slight acidity or even neutral reaction. Casts are absent, but salts and phosphates are abundant. It resembles closely the pregouty albuminuria, but differs from the latter, mainly, in the greater persistency and more regular recurrence of albumin in the latter. General systematology would also distinguish the two cases.

[1] Rev. de la Tuberculose, Dec., 1895.

[2] Semaine méd., Jan. 8, 1896.

Diagnosis.—Hodenpyl[1] urges care in examination of sputa for tubercle bacilli, warning against conclusions regarding the presence or absence of the bacilli on the examination of poorly stained specimens. On several occasions he has injected doubtful sputa into guinea-pigs, and thus reached positive conclusions. A small quantity (2 or 3 c.cm.) of the fresh sputum is injected into the groin, and the animal killed after 15 days and examined for evidences of tuberculosis. [The paper of Maragliano, noted above, is also interesting in connection with the subject of diagnosis.]

Grasset[2] employs very dilute solutions of **tuberculin** in $\frac{1}{2}\%$ solutions of phenol **for the recognition of concealed tuberculosis.** He uses $\frac{2}{10}$ to $\frac{3}{10}$ mg. of tuberculin for the first injection, and $\frac{5}{10}$ for the second. The reaction rarely passes 1°, but he considers it characteristic, and it is invariably innocuous. He reports 13 cases in which this method enabled him to make a satisfactory differential diagnosis between tubercular and other conditions. Grasset and Wadel[3] employ minute doses of tuberculin in order to recognize incipient tuberculosis. The first injection usually consisted of from 0.2 to 0.3 mg. of tuberculin, and the second injection of 0.5 mg. No bad consequences were experienced in any of 13 cases. Weber[4] reports some experiments undertaken under the supervision of Chauveau and Strauss, with the object of determining the diagnostic value of the injections of tuberculin. Experimenting particularly upon cattle, they reached the conclusion that the reaction is ordinarily more marked in animals in the early stage; that very rarely tubercular lesions were increased in activity by the injections; and that other conditions only give the reaction when tuberculosis is also present.

Ingraham[5] doubts whether **the blood of the guinea-pig** is **a certain test** for the tuberculous nature of disease, urging that material containing more or less septic matter will so reduce the general vitality of the animal as to render it abnormally susceptible to tuberculous infection from any source whatever. [This view is strikingly at variance with the general experience of bacteriologists, all of whom are convinced of the value of injections into guinea-pigs as a means of establishing *a positive* diagnosis. It is to be remembered that the lesions in such experiments are mainly glandular, not pulmonary or intestinal, as would probably be the case in accidental infection.]

Treatment.—[The use of general tonics and measures which improve the surroundings of the patient undoubtedly exercise a profound effect upon tubercular processes in many cases, even in unsuitable climates. The fact that many cases recover spontaneously is significant in the same direction.] Pepper[6] reports an interesting case of tuberculosis in which the sputum at the first examination contained myriads of tubercular bacilli. Under the treatment of **strychnin and atropin with a double chlorid of gold and sodium** all signs of tuberculosis disappeared. Later, tubercle bacilli again

[1] Brooklyn Med. Jour., July, 1895.
[2] Bull. l'Acad. de Méd., Feb. 25, 1896.
[3] Rev. de la Tuberculose, April, 1896.
[4] Bull. l'Acad. de Méd., Feb. 25, 1896.
[5] Med. Rec., May 23, 1896.
[6] Univ. Med. Mag., Dec., 1895.

appeared in the sputum after a slight attack of pneumonia. On a repetition of the original treatment the patient again became apparently entirely cured.

Mays[1] is a strong advocate of the use of **strychnin** in pulmonary tuberculosis, commencing with small doses and gradually increasing until the physiologic effects are manifested. He believes that this drug, in connection with the ordinary methods of treatment, yields a larger measure of benefit in all cases of pulmonary consumption than can be derived from any other single agent.

[**Creasote** is undoubtedly a remedy of value in many cases, though it fails signally in others or may even prove harmful.] A discussion[2] upon the value of creasote in tuberculosis was held by the Société médicale des Hôpitaux. Faisans reported a case of creasote-poisoning that simulated tubercular meningitis, and concluded that massive doses of creasote might be dangerous. Burlureaux replied that as the cases of poisoning by creasote were exceedingly rare, it was advisable not only to continue to employ it, but to employ large doses.

Faisans held that, although creasote is exceedingly valuable in cases suffering from bronchial discharge, it is contraindicated by febrile nervous conditions. It does not compare with the systematic methods of treatment, and has a tendency to persuade the patient to neglect those hygienic precautions which should receive the first consideration. Fernet declared that chronic creasotism not only tended to sclerosis of the tubercular lesions of the lungs, but also to arterial sclerosis, and cited a case in which, after prolonged treatment, the patient suffered from dyspnea and paralysis of angina pectoris. He believes that creasote is particularly indicated in patients suffering from general debility. Ferrand reached the conclusion that creasote was particularly useful in cases of torpid evolution with slight or no fever, and when the lesions showed very slight traces of congestion, but was contraindicated in cases of extensive infiltration about the foci, of extreme oscillation of temperature, and in patients with the rheumatic diathesis. Hanot declared that numerous examinations had convinced him that creasote diminished the amount of urobilinuria, and that its chief value lay in its power to diminish the mixed infections. The society decided that creasote improved nutrition and that small doses were preferable, and that it was best administered hypodermically, by injections, or in suppositories. Alger[3] found improvement in 128 cases of pulmonary phthisis among 544 patients. He found that creasote was generally the most valuable drug, and in a few cases apparently produced a cure, the bacilli disappearing from the sputum. Cinnamylic acid was also employed with favorable results in the early stages. Guiter[4] declares that the most important action of creasote is to increase the activity of phagocytosis by causing a moderate reaction of an irritating nature about the bacillary foci. Hance[5] believes that there is not enough difference between the effect of large

[1] Am. Med. and Surg. Bull., May 9, 1896. [2] Rev. de la Tuberculose, April, 1896.
[3] Am. Med. Chir. Bull., Sept. 1, 1895. [4] Gaz. heb. de Méd. et Chir., Feb. 27, 1896.
[5] Med. Rec., May 2, 1896.

and small doses of creasote to justify the physician in running the danger of disturbing the digestion by the former. Guaiacol has given fairly good results used hypodermically, but is most useful for the antipyretic action that results from its epidermic application. He still believes to a certain extent in the tuberculin treatment, using it first as a test for tuberculosis in its earliest stages, and gradually increasing the dose when it is tolerated to produce an arrest of the disease-process. After the continuous use of tuberculin for nearly five years, he thinks patients thoroughly cured by the combination of tuberculin and climate have stronger resisting power against subsequent infection than those who have obtained the same results from climatic treatment alone. Chappell[1] has used creasote for tuberculosis of the upper part of the air-tract, both internally and locally. He regards the application as a reasonable precautionary measure in cases of acute tuberculosis with profuse expectoration when quantities of mucus cling to the larynx and wall of the trachea. In 10 cases of tuberculosis with acute laryngeal symptoms, 8 died within 4 months of institution of the treatment. The result in 1 case was unknown, and 1 case was apparently entirely cured, and has remained so for some time.

Coghill[2] contributes an interesting report on the use of **guaiacol** hypodermically in pulmonary tuberculosis. This method of administration was first introduced by Schetelig, who showed it was unnecessary to dilute the remedy. Coghill has used it in a number of cases, and has found that it reduces the fever, improves the general symptoms, and sometimes arrests the course of the disease. He began with doses of ♏j and increased it as much as ♏xv. It is best to inject the remedy deeply into the muscles, and the buttocks is the most favorable situation. The fever usually comes down gradually and expectoration decreases decidedly.

Breton[3] recommends the use of injections of **guaiacol and iodoform** in the treatment of pulmonary tuberculosis. The formula of his preparation is: Guaiacol, 5; iodoform, 1; sterilized olive oil, 100. The injections were made into the abdomen or flank, and the dose was gradually increased from 15 drops to three or four times that amount, and repeated every 8 or 10 days. Walters[4] has employed creasote and guaiacol subcutaneously in pulmonary phthisis. Of 4 cases, 1 was markedly improved, 1 grew slowly worse, and 2 others showed no change. He found that the treatment was well borne and that guaiacol is not inferior to creasote.

Strauss[5] reports from v. Noorden's hospital excellent results from the use of **guaiacetin** in the treatment of tuberculosis of the lungs. The remedy is a substitution-product of guaiacol, a carboxyl radical being inserted into the methyl group of the compound. He used it in 70 cases, of which 61 bore it without the slightest disturbance of the digestive organs, though some of them had previously suffered discomfort from creasote.

[A great variety of **antiseptics** have been used in the treatment of tuber-

[1] Med. Jour., May 9, 1896.

[5] Centralbl. f. innere Med., June 20, 1896.

culosis, and the search for a specific continues, keeping pace with the activity of the synthetic chemist.]

Breton [1] has used a mixture of **olive oil and iodoform** subcutaneously in pulmonary tuberculosis. In all, 14 patients were treated, and the results seemed to him to justify the belief that the injections were useful.

Edson [2] suggests a preparation that he names **"aseptolin,"** which is essentially a solution of pilocarpin-phenyl-hydroxid in an aqueous 2.75% solution of phenol. This fluid he has used in cases of phthisis, beginning with a dose of 50 to 70 minims daily, injected into the abdominal parietes. Usually very good results were obtained, while in malaria he has used the injections with such effect that he declares the substance to be a specific of even greater efficiency than quinine. No bad effects ever followed the injections.

Knapp [3] has employed injections of **bromin and iodin** compound in cases of pulmonary tuberculosis in 5 cases. In all, at the end of 3 weeks there was notable improvement. In 3 of the cases no reaction had occurred; in 2 the treatment had been followed by a slight rise of temperature.

McTaggert [4] employs a routine treatment for phthisis which consists of the intrapulmonary injection of **ichthyol** into active tubercular lesions and the administration, either hypodermically or by the mouth, of **guaiacol.** His report includes only 4 cases. [In connection with the methods of treatment, such as the above, that depend upon the direct injection of irritants and antiseptics, we may call attention to the plan of injecting iodin suggested and used by one of the editors many years since. In some cases beneficial results followed, but the treatment is manifestly unsuited to general application.]

Fütterer [5] advocates the use of **oil of cloves** in the treatment of tuberculosis. Gelatin capsules filled with the pure oil are administered with milk every two hours from 8 A. M. to 10 P. M. If the oil is well received, another capsule is given every hour. In addition, the oil is mixed with equal parts of cold pressed olive oil and injected subcutaneously. Necrosis of the skin has occurred in some cases, but he asserts that this has not been noted when the injections were carefully performed. They appear, however, to be painful. He has treated 243 cases in the course of 5½ years, and all those in the first stage seem to have recovered permanently. He states that he has also had recoveries in the second stage and 2 in the third stage.

Garner and Leeson [6] have employed a combination of **potassium permanganate and salicylic acid.** They report 4 cases of their own with bacilli in the sputum, in which perfect recovery occurred.

McDowell [7] believes that a condition of **hyperpyrexia** is particularly favorable to the growth of the tubercle bacillus, and that therefore, in order to establish a condition of environment unfavorable to the organism, we should aim to reduce the temperature both generally and locally to a point at or below

37°, and to diminish cellular hypertaxis and thus remove the commonest cause of local heat. All these indications are met by the antipyretics of the aromatic group. Of these the most valuable is phenocoll. His own method is to administer 10 gr. of phenacetin whenever the temperature exceeds 37° until it reaches normal, and to repeat this treatment whenever another rise is impending. When the expectoration is profuse and purulent he has the stomach washed out every morning, and employs some safe and efficient antiseptic. After recovery the thermometer is still used several times daily for at least a year, and any tendency to fever must be checked at once. [It is very unlikely that remedies of this class will be used extensively. The depression that has occurred with even 5 grains of phenacetin in some of our cases has convinced us that the coal-tar products are generally unsafe.]

Paquin [1] gives a further report of **serum-therapy** in tuberculosis. He holds that the serum is only for the purpose of restoring to the organism the physical elasticity which the tuberculous process has destroyed. Its efficacy is most strikingly proved when used upon acute forms of tuberculosis, those which under ordinary treatment may be classed as hopeless from the very beginning. Two cases treated by this serum were completely cured, neither physical signs nor bacilli being left. He warns against certain complications that may arise in acute tuberculosis. Constant injections of serum may result in rheumatism, particularly in those with rheumatic tendencies, and it may be of benefit to suspend the injections and use lithia. Urticaria also occurs. A disturbance of the circulation, evidenced by the very pronounced flushing of the face, may occur during or just after the injection, and is associated with extreme dizziness and occasionally chills and headache; in no case was the heart ever affected. In 2 cases in which there existed a trace of albumin albuminuria increased. He declares that in local tuberculosis of the skin or glands the result of the serum-treatment is always beneficial. He [2] believes that the action of the antitubercle-serum is really to increase the number of leukocytes, and therefore the power of phagocytosis, which according to him is the curative force of microbic affections. He reports 3 cases of acute and 10 of chronic tuberculosis, and 1 interesting case of surgical tuberculosis involving various parts of the skeleton, in all of which complete cure is claimed. Further, the same author [3] admits that **antitubercle-serum** is far from perfect, as it cannot reach all of the complications of microbic character. He reports 13 cases of tuberculosis, in all of which the diagnosis was based upon careful physical examination and microscopic analysis, and in which fatal prognosis had frequently been made by other physicians. All of these cases recovered completely with the disappearance of the bacilli from the sputum. [In connection with this much-vaunted treatment we quote the experiments of Hewetson. It is unfortunate that advocates of measures of treatment of this kind rely so much upon their clinical experience and so little upon experimentation on animals.] Hewetson [4] made some careful tests with Paquin's antitubercle-

[1] Jour. Am. Med. Assoc., Oct. 19, 1895.
[2] Ibid., Apr. 18, 1896.
[3] N. Y. Med. Jour., June 6, 1896.
[4] Ibid., Nov. 9, 1895.

serum. The spleen of a tubercular guinea-pig killed 21 days after inoculation was crushed, mixed with distilled water, and filtered through cotton; 7 healthy guinea-pigs were inoculated with the filtrate; 2 of these were used as control-animals, and 5 regularly treated with Paquin's serum in doses of 6 minims every day. The average weight of the 5 test-animals at the time of inoculation was 442 gm., and 21 days later 403 gm. The average duration of life was 50.8 days. The average weight of the control-animals was 545 gm.; 21 days later, 477.5 gm. The average length of life in these two animals was 58.5 days. The lesions of the test-animals in no way differed from those observed in tubercular pigs, and the results seemed to justify one in concluding that antitubercle-serum has no influence in prolonging life of tubercular guinea-pigs. Bandiera [1] doubts that it will be possible to secure an efficient antitoxin against tuberculosis, as the toxins produced by the bacillus are harmless to it. Robison [2] employed Paquin's antitubercle-serum in a case of tuberculosis with temporary good results, although the patient subsequently failed and died. Encouraged by this, he employed it in 2 other cases, in both of which there was rapid softening and increase of all the symptoms, leading to death. He believes that these cases are such as those suggested by Paquin as suitable for the treatment, and argues that if they are not suitable, then 99 out of 100 are unsuitable, and that a treatment applicable only to such a small percentage cannot be valuable or popular.

Among those who have advocated Paquin's treatment the following may be referred to. Shropshire [3] has treated 25 patients with Paquin's antitubercle-serum, with improvement in all. Barber has used antiphthisin in 5 cases of tuberculosis. In all the diagnosis was confirmed by the presence of bacilli in the sputum. Marked improvement usually took place immediately after the treatment was begun, and continued in all cases to what was apparently complete cure. [The treatment suggested by Maragliano is closely allied to that of Paquin.] Blaise [4] reports a case of pulmonary tuberculosis treated by Maragliano's serum; 3 injections in all were given. After the first there was an unusual rise in the evening temperature, with a slight diminution in the following days, but a greater persistence of the fever in the daytime. After the second injection there was again a rise more prolonged than after the first. After the third injection, however, the temperature only reached 38°; there were dyspnea and signs of invasion of fresh pulmonary tissue. The second day after the injection there was a sudden fall of the morning temperature to 35°; 4 days later the condition of the patient became alarming: there were edema of the feet, extreme dyspnea, cyanosis, and irregularity of the pulse; 2 days later death occurred. The symptoms that occurred during the last days resembled those of uremia, although, unfortunately, the urine had not been tested for albumin. Even supposing that the serum produced the uremic complication, a single observation is not sufficient to discredit its use. Nevertheless, Blaise believes that this case gives rise to doubts of its value. He

[1] Boston M. and S. Jour., Jan. 2, 1896. [2] North Am. Practitioner, May, 1896.
[3] N. Y. Med. Jour., Jan. 4, 1896. [4] Gaz. Hebdom. de Méd. et de Chir., Jan. 19, 1896.

believes that Maragliano still owes us proof that the serum manufactured under his surveillance is never injurious to the living organism, and that it is really useful against tuberculosis. He claims that the results so far reported are explicable as an improvement due to hygiene. Carlucci[1] records 5 cases that he has treated with the antitubercular serum prepared under the direction of Maragliano. In all there was marked improvement, which to the present has been permanent. He concludes that the serum is innocuous, causes the drying up of the bronchopneumonic foci, and improves the appetite and the physical forces, and that its effect is gradual. Carlucci[2] reports 5 cases of phthisis in which Maragliano's antitubercular serum was used with good effect. The improvement was much greater than that obtained in other ways.

Trudeau and Baldwin[3] have made a careful investigation of Klebs's **"antiphthisin,"** and conclude that it resembles deutero-albumoses in its chemic reactions, and can be precipitated by sodium-bismuth-iodid. As a similar substance may be obtained from unplanted bouillon, it cannot be considered an altogether specific product of the tubercle bacillus. The "antiphthisin" furnished by Klebs is therefore practically highly diluted tuberculin, and has the same physiologic effects upon animals when given in sufficient doses. It possesses no germicidal power on the tubercle bacillus which can be demonstrated, and has no curative influence over the course of experimental tuberculosis in the guinea-pig. Dennison[4] reports some experiments of his with Klebs's antiphthisin, which he describes as an albuminous substance obtained from tuberculin. He reports 2 cases treated by this method in which the physical signs cleared up and the bacilli disappeared from the sputum. He considers that there are probably slight reactive effects, and, in opposition to Klebs, holds that the hypodermic dose should be smaller than the rectal dose. Ambler[5] records 7 cases of tuberculosis treated with Klebs's "antiphthisin," with marked improvement or apparent cure in all. No relapses have occurred in any of the cases. Von Ruck[6] reports 182 cases of pulmonary tuberculosis treated with tuberculocidin and antiphthisin. He divides the cases into 3 classes: 1. Those in which there are prospects for obtaining a good result; 2. Those in which the lung affections and complications are more serious and the general health much impaired; and 3. Cases in which the prognosis was on the whole quite unfavorable, the lung disease extensive, and septic and other complications often present. Of class 1, 81% apparently recovered, 16% were greatly improved, and 3% were improved; of class 2, 35% apparently recovered, 34% were greatly improved, 23% were improved, 4% were not improved, and 4% died; of class 3, 9% recovered, 34% were greatly improved, 14% were improved, 4% were not improved, and 38% died. In the majority of the cases reported a year has passed since their discharge without serious relapse. In only 1 case was there any

[1] Med. Rec., April 11, 1896.
[2] Ibid.
[3] Ibid., Dec. 21, 1896.

[5] Ibid., Feb. 6, 1896.
[6] Therap. Gaz., May 15, 1896.

reason to believe that the injection had caused increase of temperature, and in all there was considerable amelioration of the subjective symptoms, such as the painfulness of the cough and difficulty in respiration. [Von Ruck's experience is certainly flattering, but does not accord with that of others. Perhaps the climate of Asheville is as powerful for good as the remedies used.]

Coghill [1] reports a case of pulmonary tuberculosis affecting both lungs, and in which, against his own judgment, he employed injections of **tuberculin.** Some improvement was noted, but the patient finally died, apparently of heart-failure due to myocarditis. The autopsy revealed extensive cavities of the lung with a dry lining membrane, surrounded by thick, fibrous walls. Dennison [2] reports a case of tuberculous cystitis with very distressing symptoms. Tuberculin was employed, with gain in weight and improvement of all the other symptoms. Two other cases of hip-disease and pulmonary tuberculosis were also improved. Of 130 or more patients that the author has treated with tuberculin, all but 1 of 33 without softening are known to be living, and 45 out of 97 with softening of the lining tissues are still living; 27 of these cases had single or double cavities.

Tuberculosis of the vascular system is unusual. But few observations of lesions within the vessels or heart have been recorded. Leyden [3] found tubercle bacilli in the vegetations of 4 cases of recent warty endocarditis, the bacilli being found chiefly in the cells.

Hanot and Levi [4] report a case in which a tubercle of recent formation was found projecting upon the interna of the aorta at a point between the origin of two intercostal arteries. The growth began in the subendothelial tissue. The patient, a man of 61, died of pulmonary tuberculosis.

Tuberculosis of the Gastrointestinal Tract.—Brocq [5] describes a case of **tuberculosis of the soft palate.** The patient was a woman suffering with tuberculosis of the larynx. The soft palate was covered by a series of small ulcerations having a punched-out appearance; there was also considerable general infiltration. The entire velum palati was involved, though the process had lasted only 2 months. This was explained by the fact that the patient was pregnant. The author recommends lactic acid in treatment.

Sawyer [6] urges the importance in cases of suspected tuberculosis of examining the **mucus collected from the rectum** just above the sphincter ani for bacilli. When found, particularly on the surface of formed stools, these clusters of bacilli are of diagnostic significance, and can be relied on to indicate tuberculous processes in the intestine. He has himself found them in several cases when they could not be found in the sputum, or when sputum could not be obtained.

Zinn [7] records a case of a man of 28 who died of miliary tuberculosis. A

mass of tubercular mesenteric glands was found, and in the intestine were found healed ulcers in the portions corresponding to the diseased glands. The case is of interest as showing **infection through the intestinal tract.**

Shattuck[1] in a clinical lecture on **tuberculous peritonitis** reports the case of a man 23 years old who had suppurative glands of the neck followed by abdominal effusion more or less sacculated; later, fluid in the pleural cavity; then recurrence of abdominal effusion; and finally necrosis of one of his ribs. Although tubercle bacilli were not found and the fluid was not injected into an animal for diagnosis, there seems little doubt that the case was one of tuberculous peritonitis. Paracentesis of the abdomen was performed at McBurney's point on account of the localization of the fluid in the right side. The author points out that although cases of this disease have recovered, mainly under surgical treatment, medical means sometimes avail, and in the present state of knowledge he would say that surgical interference is called for when medical means have failed, but not before. He refers also to another case taken acutely ill with symptoms resembling typhoid fever and also peritonitis. Effusion took place in the abdomen, and later in both pleuræ, but under medical treatment the patient slowly recovered, and Shattuck is inclined [justly we believe] to regard this as a case of possible tuberculous peritonitis.

Tuberculosis of the Pleura and Bronchial Glands.—Peron[2] discusses the pathology of tuberculosis of the pleura. He finds that the bacillary infection is at a minimum in those cases of tubercular serofibrinous pleurisies that have the clinical appearance of frank acute inflammation. He finds, moreover, that the effusion contains certain immunizing principles; thus animals which had been protected by injections of the liquid of effusions of tubercular pleurisy died later than control animals. The prognosis depends exclusively upon the extrapleural tubercular lesions that either accompany or are caused by the tubercular pleurisy. Lannelongue and Achard[3] carried on a certain number of experiments to determine the presence of mixed infection in tubercular abscesses. They found that the presence of other microorganisms was the exception in lesions not communicating with the exterior, and the rule in open lesions. In 57 cases of the former group 51 failed to give cultures upon the ordinary medium, and all but 5 of the second group gave cultures.

Rachford[4] considers that concealed tuberculosis usually means the involvement of the **bronchial glands,** and is the characteristic tuberculosis of childhood. Symptomatically it is frequently associated with tubercular family history or history of exposure to contagion, pronounced anemia without apparent cause, irregularity and early appearance of menstruation, and scanty and pale menstrual flow, dyspnea and pain in the side on slight exercise, proneness to catch cold, abnormal dwarfishness, progressive failure of health, neurotic disease, dyspepsia, and enlargement of the external lymphatics. The early

[1] Internat. Med. Mag., Oct., 1895. [2] Revue de la Tuberculose, Apr., 1896.
[3] Ibid. [4] N. Y. Med. Jour., Aug. 10, 1895.

diagnosis of concealed tuberculosis is especially important, because it is curable, and then affords partial immunity to pulmonary tuberculosis in later life.

Channing[1] reports an interesting case of dementia with persistent high temperature of remittent type, lasting for about two years. The only cause that could be ascertained for this febrile condition was a mass the size of a lemon which was found in the pelvis. The serious condition of the patient precluded operation, but at the autopsy this mass was found to be **tuberculosis of the ovaries and tubes.** Tuberculosis had already been suspected from the fact that the temperature was higher at night, and that there was less constitutional reaction than would be expected from any other infectious process; further, that malaria had been excluded by nonreaction to large doses of quinin. [Pelvic tuberculosis has assumed considerable importance in recent years from the discovery made by gynecologists that the tubes and uterus are frequently affected. We have ourselves seen a number of such cases, and in one or two the diseased area constituted a tumor of considerable size.]

External Tuberculosis.—Fisher[2] reports the case of a nurse who cut her finger on a broken sputum-glass used by a tuberculous patient. Tubercular swelling of the finger followed, with enlargement of the glands at the elbow and axilla. In the treatment of tuberculosis he strongly advocates the substitution of creasote carbonate for pure creasote, and reports that he has not encountered a single patient in whom an idiosyncrasy against this drug was manifest. Two children, one of whom had pulmonary tuberculosis with bacilli in the sputum, and the other a child of two years suffering with tubercular enteritis with bacilli in the feces, were apparently entirely cured.

VARIOLA.

[The present year has been one of unusual importance in the history of this disease, as it marks the anniversary of Jenner's great discovery. We would refer to the splendid memorial numbers of the London Lancet and the British Medical Journal and Practitioner, but cannot here condense their contents satisfactorily.]

Etiology.—Copemann[3] discusses the etiology of smallpox and vaccinia. Inoculation with vaccinia or variolous lymph in monkeys has been very successful in reproducing these diseases. In the experiments to determine the protective power of variolous lymph, calf-lymph, and humanized lymph he found practically identical results. Specially stained specimens of clear lymph taken from the vesicles before their maturity demonstrate small bacilli, often in large numbers and in practically pure culture. These bacilli cannot be found or are very scanty in the mature lymph, on account of the spore-formation which probably has taken place at this stage. Pure cultures of a bacillus indistinguishable from that of the early vaccine lymph was obtained from the

[1] Boston M. and S. Jour., Dec. 19, 1895. [2] N. Y. Med. Jour., Aug. 17, 1895.
[3] Practitioner, Jenner Memorial Number, May, 1896.

variolous vesicles of monkeys. This bacillus could not be cultivated on ordinary media, but when inoculated upon the calf it produced vesicular eruption. Successive inoculation upon a second calf, and from this upon a child, gave practically conclusive results.

Buist[1] in a study of the bacteriology of vaccinia and variola refers to 4 different colored growths obtained from the vaccine lymph of monkeys. A bacterium of constant form is found in the clear lymph, and is probably the etiological factor in vaccination as well as in variola, but it is impossible to reproduce this bacterium by artificial cultivation. The organisms in the clear lymph he regards as spores which develop into the large forms when cultivated in solid media. These spores are distinguished from micrococci by their difference in size. The opacity of the lymph in the later stages is due to natural cultivation of the organisms.

Symptoms.—Eliot[2] has observed that there is frequently a very marked difference between the lingual and axillary reading of the temperature in cases of smallpox in the early days of the disease. He tabulates 5 cases in which this difference was pronounced, in 1 being as much as 5° F., the excess always being in favor of the lingual temperature.

Robinson[3] reports 220 cases of smallpox, in 25 of which initial rashes were present, the eruptions taking the form of erythemata and of subcutaneous hemorrhages, and were found to persist until the 6th, 7th, or 8th day. A rash having a erythematous form, but more persistent and resembling the eruption of measles or scarlet fever, occurred in 10 cases, but elevation of the eruption was never observed. The hemorrhagic form occurred in 18 cases, and took the form of numerous petechiæ confined to a comparatively small area of the skin, occurring particularly upon the lower part of the abdomen and the inner aspect of the thighs; 23, or 98%, of these 25 cases had been vaccinated, but the proportion of vaccinated to the total cases was fully 70%. A distinct relation was observed between the prodromal rash and the true eruption. The papular rash either did not develop at all on the erythematous areas or did so to a very scanty degree, and as these areas were usually expansive the cases were those of the mild type. The termination of the disease was favorable in all of the erythematous cases, and even among the hemorrhagic cases no deaths occurred.

Vagedies[4] reports a small epidemic of smallpox consisting of 15 cases. It was possible to estimate the incubation, which varied from 8 to 14 days, the usual time being 10. The prodromal stage was 2 to 4 days, and was marked by a more or less severe chill and a measles-like eruption; 4 of the cases were fatal, and all of these were unvaccinated.

Cline[5] records a curious epidemic of smallpox which occurred at the Cardiff workhouse. In many cases it was possible to fix definitely the period of incubation. In 1 this extended to 17 days. Revaccination was practised after

[1] Practitioner, Jenner Memorial Number, May, 1896.
[2] Va. Med. Monthly, March, 1896.

[4] Deut. med. Woch., Jan. 16, 1896.
[5] Brit. Med. Jour., Apr. 4, 1896.

the first case on all that would accept it, and it was found that those who refused were far more likely to be attacked and have the disease in its most virulent form.

Diagnosis.—Nichols[1] reports a case of smallpox in which the eruption occurred shortly after the appearance of a hard chancre, which simulated in every respect the eruption of secondary syphilis. Under treatment with mercury the patient convalesced. The 2d case occurred 15 days later, and at first also simulated syphilis, but later the eruption became typically vesicular. Other cases subsequently occurred which were all characteristic of variola.

Treatment.—Sternberg[2] has found that immunity to smallpox may be induced by subcutaneous inoculation of vaccine virus without the development of a vaccine vesicle, and that it is probable that the subcutaneous injection of lymph preserved in glycerol would give protection without any septic complications; and, further, that the blood-serum of immune animals contains a substance in solution which destroys the specific virulence of vaccine virus when brought in contact with it. This substance, however, is not present in sufficient amount to make the blood-serum of the immune animals available for the production of immunity in man, although it is possible that the serum may be rendered stronger by concentration. Immunity produced by the serum is effective at once, unlike that produced by the lymph, which is not effective for 8 days.

Béclère[3] reports a case of smallpox, the patient entering the hospital on the 3d day of the eruption. She received an injection of 50 oz. ($\frac{1}{50}$ of her body weight) of serum of a vaccinated heifer under the skin of the abdomen. A rapid and perfect cure ensued, without any disturbance, local or general, in consequence of the injection; 32 days after the injection desquamation had occurred. The patient had been vaccinated but once, and that was at the age of 2. [Notwithstanding these reports and others of a similar nature (see *Year-Book*, 1896), the serum treatment of smallpox cannot yet be said to have passed its experimental stage.]

Finsen[4] believes that if cases of smallpox are kept in a room from which the chemical rays of light are absolutely excluded by deep red glass windows or red curtains from the 4th or 5th day of the disease, pustulation with its consequences, secondary fever and pitting, may be avoided. The treatment must be rigidly pursued and must be begun at the earliest moment. [The author refers to the history of this method of treatment, but this was noted in the *Year-Book* of last year.]

VACCINIA.

History.—[Nothing is more certain than the justness of accrediting the scientific use of vaccination to Jenner. It is quite likely that the practice existed before his time in various places, but the world owes to him all of the benefits derived from the general introduction of this method.]

[1] Boston M. and S. Jour., Mar. 5, 1896.
[2] Jour. Am. Med. Assoc., May 9, 1896.
[3] Jour. des Practiciens, No. 14, 1896.
[4] Brit. Med. Jour., No. 1823, p. 1413, 1895.

Morgan[1] disputes the priority of Jenner's discovery, and quotes Dhanwantari, who in the "Sacteya Grantham" described the method of inoculating with cowpox to protect from smallpox, and the symptoms which resulted from such inoculation. This book was published before or perhaps shortly after the beginning of the Christian era, but was probably not accessible to Jenner, to whom is due the credit of the rediscovery and the scientific investigation of vaccination.

Etiology.—Pfeiffer[2] confirms the observations of Guarnieri and others regarding the bodies found in the lesions produced in the cornea of animals after injection of vaccine. The bodies in question were found in the epithelium and later in the connective tissue, and are neither white nor red corpuscles, degenerations of protoplasm, nor degenerated nuclei, nor centrosomes, nor similar formations, but actual parasitic organisms, either protozoa or blastomyocetes. Von Sicherer[3] has repeated the investigations of Guarnieri and Pfeiffer on injecting vaccine into the cornea of rabbits, and has obtained similar results. Multiplication of the epithelium with parasite-like bodies in the protoplasm of the cells was obtained. The author believes these are definite parasites—*Cytoryctes Guarnieri.*

Layet[4] refuses to believe that vaccinia and variola are distinct diseases. By inoculating heifers with blood and lymph from smallpox patients eruptions were caused which he looks upon as true bovine variola. The contents of these vesicles reproduce the disease when introduced into other heifers. Later inoculation with vaccine-lymph was sometimes ineffectual, but in other cases a feeble, abortive eruption resulted.

Symptoms and Effects.—Sobotka[5] has studied 88 cases of vaccination, and especially with reference to the course of the disease and the state of metabolism. There are 4 stages, as determined by the temperature. First, a nonfebrile stage of 2 or 3 days, then one of remitting fever, lasting from the 3d to the 7th day, followed by a constant moderately high febrile movement from the 7th to the 10th day, the temperature being unaffected by the number of vesicles or the intensity of the local process. The 4th period is one of defervescence. Regarding the metabolism, he found that in 7 cases the excretion of nitrogen was increased in the 2d stage, and especially about the 10th day. Leukocytosis was found from about the 3d to the 8th day, and again from the 10th to the 12th day, and onward for several days.

Piper and Schnaase[6] made a series of investigations to determine the **frequency of albuminuria** after vaccination. The observations were made upon 122 infants, successively vaccinated for the first time, 54 children revaccinated, and 127 military recruits. The urine was examined before the vaccination and on the 1st, 3d, 7th, and 10th days. Of the 122 infants, albuminuria was found in 7, or 5.073%; in none did nephritis develop. Of

[5] Zeit. f. Heilk., Bd. xiv. p. 349.
[6] Berl. klin. Woch., No. 4, 1896.

the 54 cases of revaccination, albuminuria occurred in 10, or 16.6%, while among the military recruits it occurred in 10.063%.

Fox [1] discusses the question of vaccination. In the first group of cases he refers to abortive, rapid, tardy, or spurious evolution of the lesions; to abnormal size, recrudescence, supernumerary vesicles, and generalized eruption of the vesicles, "mulberry-sore," cheloid, dermatitis, swelling of the axillary glands, and ulceration. These are not due to immature lymph, to imperfect operation, or special conditions of the patient. In the second group he considers exanthematic eruptions; in the third, the diseases resulting from septic infection through the wound; in the fourth, the simultaneous inoculations which may occur at the time of vaccination—syphilis, leprosy, tuberculosis; in the last group the disease excited in predisposed individuals by the fact of their having been vaccinated.

Edwards [2] in studying the **statistics of vaccination** concludes that the evidence shows that vaccination in infancy and renewed at the end of childhood renders the individual safe from death, and almost as safe from infection as would an attack of variola in infancy. The early vaccination without revaccination, as is practised in England, leads to more deaths from smallpox in adults than occurred in the last century. Revaccination is therefore imperatively necessary.

Ausset [3] reports an interesting case suggesting **intrauterine transmission** of immunity from vaccinia. The patient, a man of 27, was vaccinated unsuccessfully in childhood and twice at the age of 21. He was again vaccinated at 27, and developed characteristic vesicles. He stated that his mother had had variola while carrying him. From the absence of scars it seems likely that his immunity in early life was due to transmission of the immunizing substances, and not to intrauterine variola. [While the assumption of the author may be true, the facts upon which he bases his deduction are wholly insufficient.]

ERYSIPELAS.

Etiology.—Roger [4] records 597 personal observations of erysipelas. Curiously enough, he found in a number of his cases that relatives of the patients were particularly susceptible to the disease and had had repeated attacks. The great majority of the cases occurred between the ages of 20 and 50 years. The period of incubation could be determined in 41 cases. In 5 of these cases it was less than 18 hours, in 5 more it occupied from 18 to 24 hours, the longest period being 1 case in which it occupied 22 days. In this case of erysipelas, however, Roger doubts whether the incubation was so prolonged, and suggests the possibility of a subsequent infection.

Bergen [5] reports a case of general erysipelas occurring **during the puerperium,** followed by popliteal gangrene. The disease commenced in the face,

[1] Practitioner, Jenner Memorial Number, May, 1896. [2] Ibid.
[3] Bull. de l'Acad. Méd., Jan. 21, 1896. [4] Revue de Méd., Nov. 10, 1895.
[5] Med. News, Oct. 19, 1895.

and infection could not have occurred from the genitalia, as they were healthy throughout.

Treatment.—Marmorek [1] has succeeded in producing an **antitoxin** of streptococcus infection. He has used this in cases of erysipelas with great success. The mortality before this was usually 5.12%, while during the period of its use, in which 306 cases occurred, of which 165 were considered severe enough to be injected, the mortality fell to 1.63%. Omitting certain cases with severe complications or associated conditions, the mortality was but 1.2%. A weaker serum was then employed and the mortality rose 4.82%. When the dose was sufficient, improvement in the local and general symptoms took place in 5 to 12 hours and the temperature rapidly declined, becoming normal in 24 hours. If this did not occur, the dose was repeated. Albuminuria disappeared in 24 to 48 hours after the treatment commenced when it was present before. It never occurred during the treatment. The dose varied from 10 to 20 cc., and never exceeded 120 cc. in 10 days. Similarly gratifying results were obtained in puerperal fever, and especially when this was a pure streptococcus infection.

Gonion [2] reports a case of facial erysipelas occurring in a man of 50, in which Marmorek's antistreptococcic serum was injected. The first injection was made on the 3d day after sedative remedies, inunctions of guaiacol and glycerin, and laxatives had been given. His temperature was 104.5°, and the eruption had spread since the day before. The next day the general condition was improved and his fever lessened; the 2d day still further reduction of fever and general improvement, and the second injection was given; the day following this the eruption entirely subsided and desquamation followed. Tison [3] reports the treatment of erysipelas with an antistreptococcus serum of Marmorek. Of 145 cases treated systematically by the ordinary methods, 5 died; of 409 cases treated by systematic cold baths, 16 died; of 297 cases treated by a serum of medium strength, 5 died; and of 107 cases treated by a weak serum, 7 died; of 97 cases treated by a strong serum, but 1 died—the mortality being for cases not treated by serum 3.79%, and for the serum treatment, 2.59%. These statistics show that weak serum is less effective than systematic treatment, but strong serum very much more so. After the injection the symptoms diminish markedly within a few hours, and disappear completely within a few days. Albuminuria is never caused by the injections, and if it exists it disappears. Suppuration after the injection is very rare, and the glandular swellings usually resolve favorably. Nevertheless, Tison considers that the treatment by aconitin is superior to that by the serum, as he has had 100 cases without fatal results. Bolegnesi [4] points out that the statistics in this disease in particular show great variability in the severity of individual cases according as the disease occurs for the first time or has previously occurred in the same patient. The apparent effect of remedies is therefore to be governed by this knowledge. Quoting his own results, he reports 6 fatal cases among

[1] Annales de l'Inst. Pasteur, Nov. 7, 1895. [2] Lyon méd., Feb. 23, 1896.
[3] Jour. de Méd. de Paris, Apr. 26, 1896. [4] Bull. gén. de Thérap., 1896, 40e liv. p. 110.

250 cases (mortality 2.4%) in instances treated with boric vaselin; 4 deaths in 200 cases (2%) in instances treated with ichthyol ointment; 1 death in 115 cases (0.9%) treated with Renoy's method consisting, of application of icthyol-traumaticin. These results compare very favorably with Chantemesse's statistics, showing 34 deaths in 1055 cases, or a mortality of 3.02%.

INFLUENZA.

De Renzi[1] holds that there can be no influenza without **Pfeiffer's bacillus.** He refers particularly to nervous manifestations, calling attention to the frequency of headache, especially hemicrania. This may be as severe as in meningitis. Other grave symptoms simulating those of meningitis may occur, and actual inflammation of the meninges and brain is sometimes observed. Neuroses often follow. The author advises against antipyrin and advocates quinin and salipyrin.

Hennig[2] records the experiences of an epidemic of influenza during the early months of 1895. The cases could easily be grouped in separate forms—cardiac, gastric, respiratory, and nervous. Among the latter headache, prostration, and sweating were the prominent symptoms. Headache was almost invariably present, and varied in intensity and in location. Next to this the depression or prostration, often most intense and coming and going with great suddenness, was striking. Rheumatoid pains and neuralgias were common, and alterations of the heart-rhythm, traceable to affection of the vagus, were sometimes prominent. Among the remedies used for neuralgic pains salophen seemed the most efficacious.

Ferry[3] repeats and extends his remarks upon the **throat-affections of influenza.**[4] In the mean time, communications from other physicians had convinced him that the lesions observed by himself are characteristic. In the early acute stages he finds the tongue covered with a thin white coating, but specially distinguished by dark purplish-red spots, probably enlarged fungiform papillæ. Posteriorly larger elevations are observed. Later the spots turn into pinkish-white jelly-like vesicles, but on pricking these no fluid escapes. In addition to these lesions, small whitish vesicles may occur in the mucous membrane of the lips, cheeks, palate, and pharynx. [We have found similar appearances on the mucous membrane of the throat in influenza, but identical lesions occurred in cases of other diseases; so that we cannot admit the value of this sign in diagnosis.]

Complications and Sequels.—Tecce[5] reports a case of influenza in a boy of 15, which was followed by a second attack a year and a half later, and this after a few days by headache, unconsciousness, convulsions, and coma. The lower limbs were rigid, the neck was retracted, and the abdomen depressed. The calves of the legs and the back were extremely sensitive; the temperature was never high; and the pulse was slow. After 20 days the boy recovered,

[3] Lancet, Oct. 12, 1895.
[4] Ibid., March 9, 1895.
[5] Riforma Med., March 20, 1896.

and has remained well. The author regards the case by exclusion as one of post-influenzal pseudomeningitis.

Goodhart[1] records a series of 9 cases of **thrombosis** of the veins of the legs occurring in the course of influenza. He regards the latter as the immediate cause. All cases ended in recovery. [This coincides to a certain extent with the experience of Robinson, referred to last year, and there seems evidence enough to believe that grippe occasionally predisposes to or directly induces thrombosis.]

Hitzig[2] describes a case of **pneumonia** following influenza and terminating in gangrene. The bacteriologic study disclosed only influenza bacilli.

Anders[3] reports 3 cases of influenza with **typhoid fever** as a complication and sequel. In all the cases the characteristic eruption appeared and the symptoms were typical. Unfortunately, no bacteriologic observations were undertaken.

Gaeser[4] reports his experience with **quinin as a prophylactic** against influenza. Only 6 men out of a squadron so treated contracted the disease.

MALARIAL FEVER.

Etiology.—Hurley[5] reports an epidemic of malaria in his own family which was traced to the water of an artesian well. The epidemic ceased when the water was carefully sterilized, and recurred when this was omitted. Newton[6] contends that malaria may be conveyed both through the air and water. He believes that in places ordinarily malarial, drinking water is probably the more frequent cause; but in places like the Campagna of Rome or the Orinoco River of South America, in which malaria is so prevalent, the atmosphere is the method of transportation. His own observations were based upon investigations made at Fort Sill, Indian Territory, when he was the post-surgeon of the United States Army. These investigations have been previously published.[7] [Undoubtedly, the evidence warrants the belief that malaria may be conveyed through the air, and by water as well. Unfortunately, no success has attended the efforts to discover the specific organisms in soil or water.]

[It has undoubtedly been proved that the malarial organism is specific for this disease, as far as it is possible to prove such a statement without obtaining pure cultures and causing the disease in man or the lower animals. There are, however, some who remain skeptical, and from time to time adverse opinions still make their appearance.] Lawrie[8] reports a case of malarial fever in which no parasites were found until after the first paroxysm. Later, they were seen daily in the blood, but bore signs of a well-marked relationship to the white blood-cells. A roset-form that was observed for a long period seemed at first like the red blood-cell with a spot of black pigment in the center. A number of small cells then made their appearance in the form

[1] Practitioner, Aug., 1895.

[7] Med. News, July 5, 1884.
[8] Lancet, June 20, 1896.

of a roset around the small black spot, but had no nuclei. They then gradually faded away, and nothing remained but the original cell with a black spot in the center, showing that instead of being a sporulating parasite, they were nothing more than a transition form of the extracorpuscular Laveran's body. He doubts the significance of the malarial organism.

Moser[1] describes a case of supposed pernicious malaria in which microscopic examinations of the blood discovered red corpuscles having unusual contractile power and giving rise to the most varied shapes, and simulating plasmodia. These movements occurred as much as 20 hours after the blood was drawn. The author looks upon them as degenerative changes, and believes that these, in combination with free pigment which was seen, permit the presumptive diagnosis of malaria, though the parasites were not found. Certain German authors have discovered similar formations.

Thin[2] declares that there are cases of severe malarial fever in which repeated examination may fail to find the parasite in the blood from the finger end, but in which blocks of pigment in the leukocytes testify to the destructive work of a hematozoon in the internal organs. For the examination of the tissues containing malarial parasites he prefers fixation in absolute alcohol or mercuric chlorid. He also describes a method for the detection of crescent bodies in chronic malaria. Mixing 1 drop of fresh blood with a drop of filtered saturated solution of methyl green, to which 1% of acetic acid has been added, the red corpuscles are dissolved, and only leukocytes and crescents remain visible, and the latter may easily be detected by a low power. He speaks of the importance of the examination of the blood in cases of supposed sunstroke or typhoid fever. He also describes pseudomalarial attacks occurring in patients that have returned from the tropics. These cases have occasionally a slight rise in temperature and aching pains in the bones, but the blood contains no parasites; quinin is inactive.

Ross[3] examined the blood of 112 cases of fever in India, and found the malarial parasite in one form or another in 69. In 5 cases with characteristic clinical symptoms it could not be found. He believes that the Italian classification holds good for India, and in conclusion expresses himself in favor of Manson's mosquito-hypothesis.

Morse[4] reports 26 cases of malaria, in 24 of which the organism was found. All of the cases, excepting 1 from Panama, originated in the vicinity of Boston. In the only case where the period of incubation was known it was 5 days. The case of Chagres fever from Panama exhibited a type of organism never found about Boston.

Manson[5] contributes an interesting paper on the malarial organism and the manner in which infection occurs. Studying the organisms after their removal from the body, he found that the sporules which have escaped from the broken roset-form soon become flagellated, and the same thing was true of the crescents.

[1] Med. Record, Nov. 2, 1895.
[2] Lancet, 1895.
[3] Brit. Med. Jour., Feb. 1, 1896.
[4] Boston M. and S. Jour., Jan. 16, 1896.
[5] Brit. Med. Jour., Mar. 14 et seq., 1896.

He looked upon these changes as the first phase outside the body. It is not visible in blood fixed at once after removal from the body. Reasoning from analogy of the filaria, he looked to **the mosquito** for an explanation of the manner in which the malarial organisms leave the body, and Surgeon-major Ross, who investigated the subject at his instance, found that the malarial organisms are not disturbed in the mosquito's stomach, but that spheres and flagellated bodies are formed at various intervals after the blood has been sucked from the patients. A native fed on water in which mosquitoes had laid their eggs and died, developed a fever 11 days later, and his blood contained organisms; a second experiment was negative.

Laveran [1] has examined the blood of patients suffering with fever contracted in Tonquin, Dahomey, Senegal, and Madagascar, and finds the parasite of malaria as originally described by him in 1880. In some places the organism is more virulent, as in Madagascar, and the ameboid bodies are larger than ordinary. This, however, he thinks is comparable to the difference exercised by climate upon the ordinary vegetation. He has never met with the varieties described by some authors as peculiar to tertian, quartan, and irregular types of malaria.

Symptoms.—Manson [2] discusses various forms of malarial infection. He divides the pernicious attacks into the hyperpyrexial and the algid varieties. The former is characterized by delirium passing into coma and a rapid rise of temperature. It usually occurs in intemperate people. He reports a curious case of aphasia occurring in one of these attacks, and believes that this form depends upon cerebral embolism, in hyperpyrexia to the thermic centers, in aphasia to Broca's convolution, etc. The algid forms are characterized by collapse, extreme coldness of the surface, and high rectal temperature. Choleraic symptoms may appear. Another variety of malarial attack closely simulates dysentery, with bloody stools. In these cases there is probably an accumulation of plasmodia in the vessels of the intestinal mucosa. Bilious, hemoglobinuric fever is a form which, there is reason to believe, has a parasite peculiar to itself, as it may alternate or coexist with ordinary malarial attacks. The urine is malaga-colored, and is loaded with hyaline and hemoglobin tube-casts, together with a large quantity of brownish granular matter that becomes almost solid on boiling. Ayres [3] describes a remittent fever which he believes to be malaria. As he did not look for plasmodia, it is impossible to accept his diagnosis without reserve. Homem [4] describes several cases of intense continued fever, occasionally with remissions, but usually persisting for several days, that reacted very well to quinin, and which he therefore believes to be malarial.

Walker [5] records a case of **hypertrophy of the spleen** probably due to chronic malaria. The spleen reached within 3 inches of the right anterior superior iliac spine, and there was also considerable hepatic enlargement.

[1] Sem. méd., May 9, 1896.
[2] Brit. Med. Jour., Feb. 1, 1896.
[3] Va. Med. Semi-monthly, May 8, 1896.
[4] New Orl. M. and S. Jour., Dec., 1895.
[5] Indian Med. Record, Apr. 16, 1896.

Treatment with mercurial inunctions, bone-marrow and ergot, fruit of the Carica papaya, quinin bisulph., strychnin internally, resulted in reducing the spleen almost to its normal size within 2 months of its institution. Catrin[1] urges great care in the explorations of the spleen in patients suffering from malaria. Among the evil results of too great violence, rupture of the spleen must not be forgotten. His own method is to draw the fingers upward from the left illiac fossa until the edge of the spleen can be felt, the patient lying flat upon his back.

De Brun[2] has described, under the title of **"pneumopaludism of the apices,"** a form of disease of the lungs occurring in association with malaria. It may occur as an acute or chronic disease, and especially in connection with those more chronic forms of malaria in which visceral changes are not unfrequent. Women are more frequently affected than men, and nearly all cases occur in young persons. Cough and expectoration may be present or there may be scarcely any symptoms. The cough may be slight or extremely urgent, and the expectoration is generally mucoid. The physical signs are those of consolidation at the apex; the most striking feature, however, is the absence of rales. Tubercle bacilli are absent, but malarial symptoms are always noted. The prognosis is good. Two cases of an acute form were examined postmortem, but showed no lesions. In the chronic form carnification of the lung is observed.

Hemoglobinuria and Hematuria.—Plehn[3] contributes an elaborate report on the black water fever of the West Coast of Africa. (A monographic consideration of this subject by Steudel was reviewed in last year's *Year-Book.*) He reports that 26% of all deaths among white settlers since 1890 were due to this disease, and that it constituted one-eleventh of all cases of fever. One attack increases the liability to others. He noticed a tendency of the disease to follow moderate forms of malaria, and to be ushered in with severe chills, as does Steudel in the work referred to. The general symptoms are reported by both authors as practically the same. High fever, hemoglobinuria, jaundice, prostration, nervous symptoms, and nephritis develop. Plehn has examined the blood, and finds small nonpigmented parasites which show rather slow movement and growth, gradually developing into an oval body which reaches the size of one-quarter the diameter of a red blood-corpuscle. This afterward breaks into 5 or 6 small oval bodies, staining best at one pole. The roset thus formed may remain a certain time or may break up into several parts. Crescents are sometimes found in the blood. Pigment is found in the leukocytes, rarely free, and never in the red corpuscles. Regarding the treatment, Plehn holds that quinin is of no value. [This is contrary to Steudel's observations, which seem to us, perhaps, more reliable.]

Steudel[5] repeats, in answer to Plehn, the conclusion which he arrived at and published in 1894—that the proper treatment of the black bilious fever of Africa consists in the administration of large doses of quinin. The mortal-

[1] Gaz. Hebdom. de Méd. et Chir., Jan. 23, 1869.
[2] Wien. Medizin., May and Nov., 1895.
[3] Berl. klin. Woch., 1895, Nos. 25–27.
[4] Münch. med. Woch., No. 43, 1895.

ity before the use of quinin was placed at 70%. With the use of large doses (4 to 8 gm. per day), only 3 out of 31 cases under his observation perished, and 2 of these were seriously complicated when they came under treatment. Small doses, he holds, aggravate the trouble, but large doses are specific. Quinin is also a reliable prophylactic. Boisson [1] details 3 cases of hemoglobinuric fever occurring in soldiers attacked with malaria in Madagascar and transported from there to Lyons. The onset occurred from midday to midnight, and there was an intense cold stage. Jaundice was marked, though not continuous. There were marked gastric disturbances with pain in the abdomen and vomiting, and the temperature rose to 105° or more. The reduction in the number of red corpuscles was enormous, reaching 670,000 and 1,600,000 in 2 of the cases. The red corpuscles were irregular in shape, and there were shadow corpuscles in some number. There was free pigment. Malarial organisms were found in great numbers, and it was estimated that 7 out of every 10 red cells contained parasites. The urin contained no red corpuscles, but methemoglobin, oxyhemoglobin, and urobilin. The author considers jaundice to be hematogenous in origin and due to the presence of hematin in the blood. Doering [2] refers to the treatment of black water fever, and in particular, to the value of quinin in this condition. The clinical history of 6 cases is given, all of which recovered, although they received quinin in small doses. The author regards this remedy as wholly unnecessary, having no influence on the course of the disease. He administers diuretics and forced feeding. Woldert [3] reports a case of malaria characterized by exceedingly severe hematuria. Both the intracorpuscular and the crescent types of the plasmodium were found in the blood, and they were still found in considerable numbers 10 days after quinin dissolved in nitrohydrochloric acid had been commenced.

Diagnosis.—Osler,[4] after a careful study of the malarial statistics of the various cities of the United States, states that the mortuary bills dealing with malaria are inaccurate, as a result either of the ignorance or of the wilful deception on the part of those who make the returns, and he urges that care should be taken in accepting such reports unless more specific details are given, particularly regarding the plasmodium, than have hitherto been demanded.

Boisson [5] reports a symptom of malaria that he observed in a large number of soldiers returning from Madagascar. Before the development of the chill, when the temperature is already somewhat elevated, the ordinary pale pink color of the nails gives place to a pale slaty-gray color, which is distinct from the cyanosis of asphyxia, and increases with development of the chill. He reports a number of cases in which the absence of this sign enabled him to exclude malaria, and the subsequent history of the case invariably showed that his opinion was correct. He believes that it is to be explained by the

[1] Rev. de Méd., May 10, 1896.
[2] Deut. med. Woch., No. 46, 1895.
[3] N. Y. Med. Jour., Jan. 4, 1896.
[4] Med. News, Nov. 23, 1895.
[5] Med. Rec., June 21, 1896.

alteration of a greater or less number of red corpuscles which occurs at the crisis.

Treatment.—Nanjaba [1] reports 5 cases of malaria treated by solutions of phenol. In all there was prompt recovery, in several after the ordinary antipyretic treatment had failed. George Thin [2] recommends quinin in doses of 5 gr. a day as a prophylactic against the African fever. Laborde [3] believes that the most efficacious prophylactic dose of quinin in tropical regions is about 20 cgm. a day, or from 40 to 60 cgm. every 2d day.

TYPHUS FEVER.

Legrain [4] reports a number of cases of typhus fever that occurred at the civil prison of Bougie, in which injection of serum of convalescing patients was employed. [He insists that his results establish a certain beneficial action, but the reports do not seem sufficiently satisfactory to establish this view.] Somewhat encouraging results have also been reported by Chantemesse.

CHOLERA.

Hebir [5] refers to his paper published in 1892 in which he described a hematozoon as occurring in the blood of choleraic persons. After alluding to the criticisms that had been made upon his first contribution, he states that subsequent investigations do not permit him to retract anything from his previous statements. The organism described is exceedingly polymorphous, and the following forms may be recognized: large spheres with granular or hyaline contents and surrounded by cilia; small spheres (half the size of a red blood-corpuscle) with similar contents, but fewer and coarser cilia; small ameboid bodies with spore-like bodies in their interior, and a few cilia; cyst-like bodies; and star-like organisms. [It seems rather remarkable that other observers have failed entirely to discover such organisms in the blood.]

Johnson [6] replies to Macleod, who had condemned the evacuant (castor-oil) treatment of cholera. According to Johnson, the advocates of treatment to check the preliminary diarrhea would imitate the very measures by which Koch succeeded in producing cholera in guinea-pigs. Johnson therefore speaks of the opium treatment recommended by Macleod as the "Koch guinea-pig treatment." The paper of Sir George Johnson has a pathetic interest, as it was one of the things he was engaged upon on the day of his fatal seizure.

Mitia [7] states that the experience in India has been that opium in the early diarrheal stage of cholera may check the disease, but in the later stages is harmful. This view contradicts the opinion of Johnson and the similar teaching of the Hindu treatise of medicine, the *Midan.*

Haffkine [8] proposes the term **variolization** for the process of using infectious virus taken from a patient suffering with cholera to produce immunity,

[1] Indian Med. Rec., Aug. 16, 1895.
[2] Lancet, Jan. 25, 1896.
[3] Bull. de l'Acad. de Méd., Paris, Feb. 11, 1896.
[4] Gaz. des Hôpitaux, July 4, 1895.
[5] Indian Med. Rec., July 16, 1895.
[6] Lancet, June 13, 1896.
[7] Indian Med. Rec., July 16, 1895.
[8] Brit. Med. Jour., 1895, p. 1541.

and the term vaccination for the employment of a vaccine produced by cultivating microbes and maintaining them at a fixed state of virulence. The latter method is the one employed by himself. He uses 2 injections—the first mild, and the second, after an interval of 5 days, a moderately strong one. The full effect of these is not observed until 5 days have elapsed. He has made 70,000 injections on 42,179 persons without a single mishap. The result has invariably been favorable when large numbers of persons had been exposed. Applied during an epidemic, it tends to reduce the mortality even during the first ten days. Antitoxic treatment he considers a decided success, but useless as a preventive treatment, since its effects on the system are rapidly worn out.

Behring and Ransom [1] have prepared from cultures of cholera bacilli, by separation of the bacteria themselves, a liquid having toxic power. By injection of the latter into guinea-pigs, sheep, and goats, after the methods employed in immunization, antitoxic serum was developed.

YELLOW FEVER.

Finley [2] regards the micrococcus tetragenus versatilis of Sternberg or tetracoccus versatilis as **the specific organism** of yellow fever. The organism is easily obtained in pure cultures from the serum of blisters, from the excreta, or from the milk of patients suffering with this disease. It is also obtained from mosquitoes which have fed upon patients. Pure cultures are pathogenic for animals, the symptoms in the latter occurring in two paroxysms, and death following in 5 to 9 days. Direct contagion from one rabbit to another in the same cage was observed.

Finley [3] suggests that individuals not acclimated may be rendered immune from yellow fever by inoculation with the aid of **mosquitoes.** Of 100 persons thus inoculated in the course of the last 14 years, only 3 have subsequently perished by yellow fever.

DYSENTERY.

Walsh [4] denies that it is conclusively proved that the amœba coli is the cause of tropical dysentery. He has found these amebæ in cases that were certainly not dysenteric, and even in those in which there was no disease. In speaking of treatment, he considers emetin the valuable element of ipecac, and has given it in combination with the biniodid of mercury. Of 39 cases treated by this method, but 1 died. The average duration of the disease was $4\frac{1}{2}$ days; of 10 cases treated with the bark and seeds of Holanhena antidysenterica, all recovered, with an average duration of 5.7 days. He regards a mixture of solution of sulphate of magnesia and aromatic sulphuric acid as the best treatment. [There can be no doubt of the occasional occurrence of amebæ in the stools of healthy persons or of individuals suffering with ordinary diarrhea, and the investigations of Cunningham have proved that the organisms in question are common in the dejecta of horses and cattle. Nevertheless, the evidence is very

[1] Deut. med. Woch., No. 29, 1895.
[2] Edinb. Med. Jour., Dec., 1895.
[3] Ibid.
[4] Indian Med. Rec., April 16, 1896.

strongly in favor of the view that the amœba coli is pathogenic in dysentery.]

Young[1] discusses the **amebic catarrhs** of the intestinal tract. He reports 3 cases, in 2 of which autopsies were held, and amebæ were found in great abundance in the distended bile ducts. In the other cases improvement occurred with discharge of greenish fecal masses which were found to be largely composed of bile and filled with amebæ. [The discovery of amebæ in the bile is certainly quite remarkable, and requires confirmation.]

Manner[2] reports a case of dysentery followed by **abscess of the liver** in which the amœba coli was found in the abscess-cavities, though none was discovered in the intestines postmortem. The patient had always lived in Vienna. He had suffered for a year with diarrhea, the stools occasionally being bloody. Amebæ were found in the stools. Evidences of an abscess of the liver developed, and the patient died soon after admission. The abscess contained numerous cavities, evidently of different periods. The oldest were encapsulated.

LEPROSY.

Kaurin[3] strongly maintains the contagiousness of lepra, and instances the increase of leprosy in islands in which it had become restricted, and in which in consequence care was not taken to maintain strict isolation.

THE PLAGUE.

Kitasato[4] reports the discovery of a bacillus in the blood, glands, and organs of patients suffering from bubonic plague. These bacilli were found encapsulated, the ends staining more deeply with aniline dyes than the middle parts, and mice inoculated with them died in 2 days, showing great edema around the point of inoculation.

Lowson[5] states that an epidemic commenced in Canton in February and reached Hong-Kong in May. The disease is a specific, infectious fever characterized by the presence of a definite bacillus, and primarily affecting the lymphatic system and afterward the cerebral and vascular systems. The chief predisposing causes are unsanitary or unhygienic surroundings. Infection takes place through the discharges from the patient, and skin-infection is impossible unless the one to be infected has some wound that is soiled by discharges or the blood. The poison is not carried by flies and mosquitoes. The period of incubation is from 3 to 6 days. The early symptoms are malaise; later the fever becomes higher, the temperature rising often as high as 106° F. Decline takes place by lysis or less frequently by crisis, and antipyretics have slight if any effect. The inguinal glands are most frequently affected, although all the glands may show more or less enlargement, and are then surrounded by a considerable amount of serosanguinolent exudation. When the mesenteric

[3] Centralbl. f. innere Med., Sept. 28, 1895.
[4] Preliminary Notes of the Bacillus of the Bubonic Plague, Hong-Kong, 1894.
[5] Epidemic of Bubonic Plague in 1894, Hong-Kong. 1895.

glands are enlarged there is frequently considerable abdominal pain. Cerebral symptoms appear early, and are usually due to meningitis or hemorrhages. Four types of brain-symptoms may be differentiated: those in which the patient is comatose, wildly delirious, apathetic, or has convulsions. Sudden heart-failure may occur, probably due to organic changes in the heart-muscle itself. In the early stage the pulse is full and bounding; in the 2d, dicrotic; in the 3d, anacrotic; and in the 4th, the pulse of collapse. There is no eruption, hematemesis is rare, and hematuria has never been noticed. In a few cases there was some conjunctival ecchymosis. The tongue is at first dry and almost covered with thin white fur, which later becomes thicker and changed to yellow-brown or black color. The buboes occasionally underwent resolution, but usually the period of enlargement was persistent, or suppuration or even sloughing occurred. The diagnosis is to be made by the discovery of the characteristic bacillus. The treatment is purely symptomatic. During this epidemic the death rate was 93.4%. Amongst Hindus it was 77%; Japanese, 60%; Eurasians, 100%; Europeans, 18.2%. The diminished mortality among the latter is probably due to the superior attention that they received. Death occurred as the result either of sudden heart-failure or as the result of hemorrhage or pyemia. During the convalescence the tissues of the body showed little reactive power, wounds healing very slowly, particularly those resulting from incisions of the buboes. Altogether, 2679 cases were treated in the hospital, of whom 2489 died.

Mahe[1] reports the principal appearances of the plague in the last 10 years. Of these 3 were in the British Empire, 2 in Persia, and 3 in China. In the last 40 years he claims that there were 150,000 deaths in China alone, and altogether about 300,000.

ANTHRAX.

Jaworski and Nencki[2] report a case of anthrax which presented the clinical manifestations of purpura hæmorrhagica, the hemorrhages having taken place mainly from the gastrointestinal tract. The patient, a young man of 36, first noticed an ulcer on the left leg which had caused considerable pain. The more violent symptoms occurred some time later, but the authors incline to believe that the primary infection took place from the gastrointestinal tract rather than from the lesion upon the leg.

Blumer and Young[3] report a case of anthrax septicemia in a man of 59, who worked in a factory in which hair brought from South America was used. He infected himself by rubbing his eye with his hand. The next day his eye was swollen, and bacteriologic examination discovered anthrax. The case ended fatally, and the bacilli were found in the organs. Acute endocarditis and peritonitis were among the lesions.

Krumbholz[4] reports a case of intestinal anthrax with choleraic symptoms.

[1] Bull. de l'Acad. de Méd., Paris, Apr. 21, 1896. [2] Münch. med. Woch., July 23, 1895.
[3] Bull. of the Johns Hopkins Hosp., 1895, Nos. 54 and 55.
[4] Ziegler's Beiträge zur Path. Anat., Bd. xvi. H. 2.

Bacilli were found in the peritoneal exudate and the blood, and microscopic examination showed that they had entered through the lymphatics.

GLANDERS.

Bares[1] reports a case of glanders in a man employed in skinning dead animals. The infection took place from a finger wound, and pustules were subsequently found in different parts of the body. The autopsy showed the characteristic lesions, and bacteriologic investigation the characteristic bacillus.

FOOT-AND-MOUTH DISEASE.

Bligh[2] records a case of foot-and-mouth disease occurring in a boy of 13. He first complained of soreness in the mouth, and the next day the mother noticed swelling of the lips and small lumps on the inside. Subsequently small blisters occurred in the mouth, and afterward vesicles appeared upon the hands. The eyelids became swollen and presented the appearance of eczematous blepharitis. There were moderate fever and other constitutional disturbances. After considering the various diseases which might present features such as those in his case, he concluded that the disease was foot-and-mouth disease, from the distribution and character of the lesions, its life-history, the associated involvement of the hand and mouth, the absence of prodromal fever, and finally from the bacteriologic study. This was conducted by the Clinical Research Association, and showed the presence of staphylococci, but particularly abundant streptococci resembling those described by Klein as pathognomonic and specific for foot-and-mouth disease among cattle.

HYDROPHOBIA.

Hayes[3] reports a case of rabies following an injury to the right hand. There were frequent and violent laryngeal spasms, particularly on any attempt to swallow. Subsequently the patient became maniacal, and had strong muscular contractions tetanic in character. True hydrophobia did not exist, the patient having the greatest desire for water, and only refusing it after a painful experience with the spasms.

Fabricius[4] reports a case of hydrophobia developing 7 months after infection. The scar became red, was tender, and surrounded by an area of inflamed tissue. Toward the end of the disease the absorptive processes must have been at a standstill, for 5 grains of morphin and $\frac{1}{2}$ grain of hyoscin produced no effect. Although the man continually ground his teeth, he never tried to bite the attendants. Another patient, who had been bitten by a dog a week before administration, but who had been drinking heavily for 3 months, was brought in, wildly maniacal, barking and making fierce efforts to bite the attendants; water produced laryngismal spasm, but milk could be readily drunk. Morphin and hyoscin acted promptly.

SEPTICOPYEMIA.

Pane[1] reports an interesting case of streptococcæmia acutissima. A man of 53 suffered a chill, followed by high fever, then deep coma, weak pulse with cyanosis, rapid respirations, and death 44 hours after the onset. The blood taken from the finger during life showed no microorganisms, but after death dry preparations of liquid from the lungs, spleen, and bone-marrow showed microorganisms presenting the appearance of streptococci. The postmortem examination showed hyperemia and edema of the brain, enlargement of the heart, edema of the lungs, and enlargement with beginning fatty degeneration of the liver. The kidneys showed beginning brown induration, and the spleen was enlarged, of a dark-red color and soft, the cells of the pulp being degenerated. In cases of acute septicemia of this character, in the absence of abscess, erysipelas, and the like, infection through the lungs should be considered.

Port[2] reports an instance of septicemia following extraction of a tooth. The patient, a young man of 22, had suffered pain in one of the lower molar teeth for a fortnight. The tooth was extracted by a friend, shortly after which a recurrence of pain brought him to the author's attention. Irregular fever developed, and the patient finally died with the evidences of general sepsis. At the autopsy it was found an abscess had developed the size of a walnut at the angle of the lower jaw on the right side. Bacteriologic study of the pus showed the presence of streptococci and bacilli.

Bujwid[3] reports a case of general pyemia with abscesses in the muscles, secondary to specific urethritis, and in which the gonococci were found in pure cultures in the abscess. [Other instances of gonorrheal septicemia will be found in the sections on Endocarditis and Pleuritis.]

Dennig[4] contributes a study of the septic diseases and reports a number of cases. The symptomatology may be studied under the following headings: 1. General symptoms; 2. The cardiac diseases; 3. The affections of the bones and joints; 4. Conditions of the skin, subcutaneous tissues, and muscle, mucous and serous surfaces; 5. Pulmonary, gastric, intestinal, and other visceral symptoms; 6. Conditions of the central nervous system. Regarding the cardiac conditions consequent upon sepsis, he finds severe endocarditis and sometimes pericarditis. Multiple abscesses and fatty degeneration of the heart may occasionally occur, and in cases in which no macroscopic changes are apparent the dissociation or fragmentation of the muscle-fibers of Renaut may be present. Regarding the joint-conditions met with, it is of interest to note that the author places himself among those who incline to regard rheumatism as a form of mild sepsis. He calls attention to the necessity of repeated examinations of the urine, insisting upon the fact that nephritis frequently develops insidiously, and may suddenly occur without previous warning in the way of symptoms.

[1] Rivista klin. e Terap., June, 1895. [2] Münch. med. Woch., Sept. 10, 1895.
[3] Centralbl. f. Bakt. u. Parasit., Bd. xviii. H. 14, 15.
[4] Deut. Arch. f. Klin. Med., July 18, 1895.

Etienne[1] reports 2 cases of pyosepticemia in which staphylococci were found in the blood, but in which there were no definite organic lesions, and in which the source of infection was not discovered. In both cases irregular fever, lassitude or depression, rigors, and the like were marked symptoms. Both cases recovered.

Chauffard and Ramond[2] report 2 cases of septicemia due to the micrococcus tetragenus. The first case was that of a girl of 5, in whom, after grip, a polyarthritis occurred affecting the hips, knee, thumb, shoulder, and elbow joints. There were chills, dyspnea, and an erythematous skin-eruption, and the patient died on the 11th day. The 2d case was that of a man who suffered with chills, nausea, and headache, followed by great swelling of one knee, and later by infiltration of the hip and leg on the same side and enlargement of the inguinal glands. An ulceration was found on the tongue opposite a carious tooth. The patient died on the 10th day. At the autopsy on the first case lesions of general infection were present—pericarditis and pleuritis, foci of purulent myocarditis, ulcerative endocarditis. In the second case no autopsy was made, but cultures were obtained from an ulcer of the tongue and from the infected knee.

Cameron[3] reports the case of a child born in the hospital and abandoned when a week old. At 12 days it began to have diarrhea and lost weight. During the 5th week a blue papule appeared on the abdomen, and subsequently 2 others. The ear discharged slightly and the body became blue, the limbs rigid, and the temperature ranged from 94° to 100½°. Two other cases similar to this had previously occurred, and Dr. Hammond obtained pure cultures of bacillus pyocyaneus from all the cases. In the last, however, other pyogenic organisms were found in the spleen and heart's blood, but pure cultures were obtained from one of the purple spots. Cameron sums up the symptoms of these affections as follows: marked and rapid wasting; diarrhea with gastric and enteric catarrh; moderate fever, ranging 2 to 3 degrees; albuminuria (this not yet observed in infants, but always present in rabbits); a bluish papular eruption, sometimes becoming pustular; and nervous disorders, such as spastic palsy, occurring late and attacking only the lower limbs.

Dennig,[4] in his article upon acute septic diseases, lays down the following as the most important measures of **treatment**: Absolute rest in bed must be insisted upon, especially when there is tendency to cardiac weakness, and the nutrition of the patient must be kept up by abundant food. Albuminous foods in easily assimilable forms constitute the best nutriment, and alcoholics may be useful. In case of cardiac weakness stimulants may be used. The pains are controlled by phenacetin in 0.5 gm. several times daily. Various other conditions require special treatment, and particularly must the secretion of urine be kept up to prevent uremia; for this purpose diuretin has proved useful.

INDEFINITE INFECTIOUS DISEASES.

Hughes[1] reported upon the **endemic fever of the Mediterranean** before the Royal Medical and Chirurgical Society. It is endemic in various parts of the Mediterranean littoral, and probably elsewhere; occasionally localized epidemics occur. It was first described by Marston in 1861. Clinically, there is irregular temperature, consisting of paroxysms of fever of remittent type, separated by apyretic intervals. This gives a relapsing character to the disease. The duration is long and indefinite, the usual stay in the hospital being 90 days. Progressive anemia, constipation, swelling and effusion of the joints, profuse sweating, and tendency to neuritis are marked features. The spleen is enlarged and soft and the organs congested, but the intestines are free of ulceration. The microorganism discovered in 1886 by Bruce is said to be present constantly. The disease prevails during the dry hot months; but it is not contagious, and no connection seems to exist between its prevalence and the supply of water, milk, or food. The infection seems to enter the system with the inspired air. Its prevalence is in inverse ratio to the amount of rain, and the mortality does not exceed 2%. In the discussion Thin stated that he had made careful examinations of the blood and had failed to find malarial organisms; he further referred to a similar fever not malarial in character recently described in Hong-Kong.

Thresh[2] records a number of **epidemics of sore throat** occurring in schools, the majority of which were characterized by the appearance of a grayish false membrane about the follicles of the tonsils and by the absence of Löffler's bacillus. Other attacks simulated scarlet fever, but the course of the disease remained benign. He is inclined to think that the former type is probably a disease having distinct specific characteristics, and, as it is undoubtedly infectious, almost certainly due to some microorganism. He also describes a pseudomembranous formation that he collected from the throats of 4 patients at different periods, and which consisted almost entirely of spherical cells—apparently a form of torula. Dr. Cline, who examined cultures of this growth, regarded it as a thrush-fungus.

Palamidessi[3] records an interesting instance of an acute seizure affecting 5 members of a Florentine family. Prostration, headache, fever, delirium, and the typhoid condition were noted. The spleen was slightly enlarged, and there were rales in the back parts of the lungs. Pneumonia appeared in 3 or 4 days. Three of the patients died within 10 days after prolonged coma. Pneumonic patches were found in the lungs and slight fatty degeneration in the kidneys. The other cases recovered. Every possible cause was excluded, but it was found that a recently imported **parrot** had been received in the house and had died shortly before. This recalled the fatal epidemic of pneumonia which occurred in Florence a few months before in association with an infectious disease of imported parrots. The author obtained some parrots suffering with this disease, and made cultures which he compared with cultures

[1] Brit. Med. Jour., Apr. 18, 1896. [2] Lancet, Aug. 17, 1895.
[3] Il Policlinico, Nov. 15, 1895.

obtained from the mouths of his patients. These studies led him to conclude that some of the microorganisms resembled fowl-cholera; they, in certain respects, resembled the bacilli obtained by Nocard from parrots dead of a specific disease, and in other respects they resembled microorganisms found in parrots by Eberth and Wolf.

SIMPLE CONTINUED FEVER.

DaCosta[1] contributes a paper upon protracted simple continued fever, and reports 2 cases. The first was a young girl with poor digestion and irritable stomach who was treated a number of years before. After a short time the digestive disturbances yielded, but an unexplainable fever arose that lasted for 3 months, never being high nor accompanied by chills or other peculiar features. Beyond the extraordinary fever there was nothing to note. Finally, after 3 months, it ended and convalescence was rapid. The 2d case was a girl of 14 who was ill with a fever for 12 weeks. The temperature was almost 105° for the first 3 weeks. Later it gradually declined and disappeared. There were no peculiar symptoms or signs of any kind excepting the fever. In neither of these cases had quinin any effect; in neither were there evidences of typhoid fever, of influenza or local diseases, and the author therefore reports them as examples of the most protracted cases of simple continued fever he has encountered. He refers to other cases of shorter duration, varying from one to a few weeks, and states that the more pronounced cases of this character occur in brokers and speculators in times of commercial panic, and that delirium is not an unusual symptom. Taking these cases as a text, the author enumerates and discusses diseases in which similar long-continued fever may take place. Typhoid fever naturally comes first, but rarely lasts as long as 3 weeks unless complications or relapses occur. The symptoms are rarely so completely absent that the fever alone would remain as the important manifestation. Remittent fevers and relapsing fevers occasion little difficulty when the blood examinations are practised. Typhomalarial fever resembles typhoid in its enteric symptoms. The continued fever that sometimes follows remittent fever may resemble simple continued fever closely. The chills and chilly sensations, disturbances of the digestive organs, and irregularity of temperature are distinguishing marks, and the malarial organisms are found in the blood. Most confusing of all are the cases of continued fever due to influenza. These may be very protracted, and may be wholly unaccompanied by other symptoms, or may be attended by involvement of the gastrointestinal tract. The author further alludes to forms of continued fever found in various localities and regarded as different from typhoid, introducing these with the remark that he still believes in the existence of a continued fever of considerable duration that is not typhoid—only a malarial fever that has become continuous—notwithstanding his full appreciation of the difficulty in distinguishing and recognizing typhoid in certain cases. He refers to the ardent fevers of the tropics of which the inflammatory fever of Copland and the thermic fever of Guitéras are varie-

[1] Am. Jour. Med. Sci., June, 1896.

ties; to asthenic simple fever of Murchison; to starvation-fever previously described by himself; to Malta fever; to continued fever previously described by Cain at Nashville; and to Cyprus fever and the simple continued fever reported by Baumgarten at St. Louis. The last two, however, are particularly questionable. Next he enumerates the various symptomatic fevers arising in connection with local diseases. Among these are miliary tuberculosis, fecal impaction, anemia (chlorosis and pernicious anemia), hysteria, chorea, rapidly advancing arteriosclerosis, disease of the endocardium or of the lung and pleuræ, or duodenal catarrh. From all of these conditions he distinguishes protracted simple continued fever. In this the lesions are absent and the spleen is not markedly enlarged. Occasionally meningeal exudation has been noted. Regarding the causation of these cases, the author inclines to the view that they are forms of autointoxication, and suggests that the poisons may be leucomains of the uric-acid group.

FOOD-INFECTIONS AND INTOXICATIONS.

Vaughan and Perkins[1] in a paper on food-infection refer to 3 cases under their observation. The first, a vigorous man of 34, ate canned salmon, and 8 hours later suffered nausea, vomiting, and griping pains. A scarlatinous rash covered the entire surface of the body. The pulse was 140, the temperature 102°. Thorough lavage of the stomach and large intestines was practised, and 10 gr. of calomel, followed by 12 ounces of solution of magnesium citrate, were administered. The bowels acted freely and the patient recovered, although the temperature remained above normal for 4 or 5 days. Chemical examination showed the absence of inorganic poisons, and bacteriologic study revealed a micrococcus, which, however, in beef-tea cultures was nonpathogenic. When cultivated after Hueppe's anaerobic method it produced a potent poison. Subcutaneous injection of liquid expressed from the salmon caused evident illness and suffering in a white rat. In the second instance the father, mother, and two children suffered with vomiting and marked exhaustion, but without fever or diarrhea, after a supper of which dried beef made a part. Anaerobic cultures from the interior of the meat developed a bacillus 2 or 3 times as long as broad, motile, not liquefying gelatin, but coagulating milk. It grew best at the temperature of the body, and developed its poison at the ordinary temperature. It was pathogenic to white rats and guinea-pigs. In the third instance a number of men at a banquet were affected. All those who ate of pressed chicken, and some persons not at the banquet, but who aided in preparing for it and ate small parts of the chicken, became ill. The attacks began 2 to 4 hours later with nausea, violent griping, and purging. Many fainted while attempting to rise from bed. The chickens had been killed Tuesday, and were not used until Thursday. Two microorganisms, a slender bacillus from four to five times as long as broad, and a streptococcus, were developed. The bacillus was fatal to white rats, guinea-pigs, and rabbits; the streptococcus was not fatal, but caused sloughing.

[1] Med. News, Nov. 16, 1895.

Brosch [1] reports a case of fatal poisoning by **oysters.** The patient suffered with vomiting, vertigo, paralysis of the muscles of the throat, the pupil, and of the face, with paralysis of the walls of the bladder and general weakness. Consciousness was preserved until the last. Postmortem there were edema of the brain and pia, and small punctate hemorrhages in the central nervous system and in the serous surfaces. Analyses of the stomach-contents showed ptomains, but these had no special characteristics. The hemorrhages noted in the case the author holds to be due to the mode of death—viz. failure of respiration. The symptoms are the same as those found in some 13 cases of fish-poisoning which have been published. Finally, he points out that poisoning by meat or fish may occur in two forms, excluding the mildest cases: In the first form true gastroenteritis with high fever and colic are the important symptoms, and the cases usually recover. These cases are due to intestinal infections with bacteria. In the second form the symptoms are those observed in the reported case, in which fever is absent and constipation caused by intestinal paralysis occurs instead of diarrhea. This form is toxic in nature, and should be treated by irrigation of the stomach and intestinal artificial feeding, frequent catheterization, and artificial respirations continued until the poison is eliminated by the kidneys. Bell [2] records a case of poisoning by canned oysters which occurred in 3 of a family of 4, the fourth not having partaken. Chatin [3] states that there are 4 varieties of toxicity which may be ascribed to oysters—that which occurs in connection with chromatism; that which occurs at the reproductive periods; that due to tissue-alterations; and that due to external conditions. Particularly in the latter case it is important to prevent the water in which the oysters grow from being contaminated, and he cites an interesting epidemic of severe cardialgia, colic with attacks of vomiting and diarrhea, and fever, which followed contamination from the presence of a garrison near the water.

Cameron [4] reports an epidemic of vomiting and purging in 74 nuns and girl pupils in a convent at Limerick. The only article to which suspicion could be attached was some custard, and this, given to pigs, induced severe diarrhea. The **eggs** from which the custard was made were stale.

GENERAL CONSIDERATIONS REGARDING THE INFECTIONS.

Fever.—At the German Congress for Internal Medicine, held April, 1896,[5] a most interesting discussion was held upon the nature and treatment of fever. Unverricht of Magdeburg, after considering the various theories of the nature of the fever, concludes that this term should be applied only as indicating the elevation of temperature: no invariable symptoms accompany the fever, and no uniform underlying cause is discoverable. In the discussion von Jaksch pointed out that, besides elevation of the temperature, alteration of the tissue-metabolism is a constant and important symptom. Kast calls attention to the fact that

[1] Wien. klin. Woch., Mar. 26, 1896.
[2] Med. Rec., Dec. 21, 1895.
[3] Bull. de l'Acad. de Méd., June 9, 1896.
[4] Dublin J. of M. Sc., Oct., 1895.
[5] Centralbl. f. innere Med., Apr. 25, 1896; Berl. klin. Woch., Apr. 20–27, 1896.

elevation of temperature may prove a conservative process, and in particular pointed out that animals inoculated with typhoid cultures and kept at a temperature of 36° died, while those in which fever was maintained at 40° and 41° recovered. Unverricht in the discussion emphasized the same points—namely, that high temperatures are not of necessity dangerous, and that, on the contrary, they may have a protective action. Jennings[1] believes that the antipyretics find their true place in the early stages of acute sthenic fevers, but are contraindicated in prolonged fevers of adynamic type. Hare[2] expresses the opinion that moderate fever not only is not harmful, but that it is a protective against infection and aids in the production of immunity. Regarding treatment, he holds that cold baths do good, not by the mere abstraction of heat, but by increasing metabolism and the rapidity of all vital processes, and that the use of antipyretic drugs is contraindicated in all infectious diseases.

Climatic Influence.—Jeannel[3] reports that the excess of deaths over births is 9 times as great in the 30 departments of France which have been deprived of their forests, as it is in the 57 others, and that these departments are particularly subject to severe and devastating epidemics of infectious diseases, such as tuberculosis, cholera, diphtheria, etc.

Treatment.—Chelmonski[4] prepared an extract of putrid meat that he employed in various infectious diseases. All of 25 cases of typhoid fever recovered, although the mortality in the hospital for the 2 years during which these cases occurred was 20 and 18%; 9 cases are reported at length, in 4 of which the temperature fell by crisis, and in 5 by lysis. All the other symptoms improved proportionately. Of 42 cases of typhus, but 1 died, although the general mortality of typhus in the hospital was 07.7%; 8 cases are reported at length, and among these was Chelmonski himself, who had sufficient confidence in his treatment to order the injections given. The general results of the injections were, first, a perturbation, then a more or less rapid decline of the temperature curve and improvement of the general condition of the patient. In certain cases the treatment did not seem to be indicated, particularly those in which there were marked symptoms of nervousness or hysteria. Smallpox, scarlet fever, and pulmonary consumption were treated by the extract without result, but a few cases of erysipelas and pneumonia were apparently benefited. He comes to the following conclusion: that the intramuscular injections are neither dangerous to life nor in any way injurious, and the injections exercise a certain influence upon many infectious diseases, shortening the duration and improving the symptoms. The extract in the form in which he uses it is not generally applicable for therapeutic purposes, first on account of the unknown factors that cause variations in its action, and second, on account of the impossibility of preserving it. Lesser[5] urges the exclusive use of water as the only nourishment in all febrile diseases during the period when the temperature is high (above 104° F.). He always com-

[5] Med. Rec., Oct. 19, 1895.

mences treatment by lavage of the stomach. He reports 17 cases treated by his method, all of whom recovered.

Theodore Beyer[1] has made some extensive experiments with **trional as a hypnotic** in various febrile diseases. Usually a deep sleep of from 5 to 6 hours' duration is produced by a dose of 1 gram. A disagreeable feeling, headache, and vertigo were sometimes very marked, but nausea and vomiting were not observed. In patients severely ill the remedy proves ineffectual.

Chantemesse[2] uses **rectal injections of the various curative serums,** and finds that they are as valuable as equal doses injected hypodermically.

Fraser[3] has made a series of experiments in order to determine how far it is possible to cause immunity to snakebite. An **antivenene** was prepared by gradually accustoming a horse to the action of the poison, and it was found that, mixed with venom in vitro and then injected, it was possible to prevent toxic action. If the injections were simultaneous, but separate, larger quantities of the antivenene were required, being smaller if the injection was made half an hour before the venom is administered and larger if made half an hour afterward. The antivenene was also effective in producing immunity when administered by the stomach, and it was found that the venom itself when so administered failed to produce any toxic symptoms, but that the animals were subsequently immune.

DIATHETIC DISEASES.

RHEUMATISM.

Etiology.—[The nature of rheumatism is still unsettled. It is included among the Diathetic Diseases in deference to custom rather than from a firm conviction that it is a chemical disorder. All of the recent investigators incline to accentuate the importance of infectious influences, and it seems well-nigh established that the disease is occasioned by specific microorganisms. The life history, nature, and manner of entrance into the system of these microorganisms require further demonstration, but the single fact of the infectiousness of the disease may be considered as practically settled. Doubtless, however, favorable conditions of the system and an inherent predisposition on the part of certain individuals are important factors. The following abstracts indicate the views entertained by various investigators.]

Humphries[4] believes that the poison of acute rheumatism is one which may manifest its presence in a number of ways, of which rheumatic fever is the severest form. The characteristics of these manifestations are a tendency to relapse, to recur, and to rapid improvement under the salicylates. He generalizes notes of 240 cases occurring in 160 patients. He first endeavors to prove that the minor manifestations, such as tonsillitis, etc., are apt to show themselves as complications of a rheumatic attack, and reports 13 cases in which this occurred; next, that all these forms have a certain period of incu-

[1] Wien. med. Bl., Aug., 1895.

[3] Brit. Med. Jour., Apr. 18, 1896.
[4] Med. Press and Circular, Nov. 6, 1895.

bation, and he reports 23 cases in which a period of malaise had lasted from 7 to 21 days previous to the onset of the symptoms: 55 cases of other rheumatic affections also had prodromal symptoms. Lastly, he reports a number of cases in which the rheumatic manifestations appeared in persons thrown in contact with one another at intervals corresponding to the periods of incubation.

Chvostek [1] has investigated the etiology by making cultures from the urine removed with antiseptic precautions. He examined 12 cases, but with positive results in only 3, finding staphylococcus albus in the first, a diplococcus in the second, and a large undescribed coccus in the third. He had positive results only in cases of sepsis and gonorrhea, and concluded that the alterations of the joints are due, not to the direct action of bacteria, but to the effects of toxic substances, the latter being produced at various points. They may be caused, for example, by bacteria in the intestines, which are otherwise nonpathogenic. He does not deny the occurrence of bacteria in certain joint diseases, but questions the propriety of applying to them the term rheumatic. Regarding the seat of infection, he inclines to believe that the tonsils and intestines are the most frequent.

Singer [2] has examined the urine in 17 cases, finding staphylococcus albus in 10, s. aureus in 1, streptococci in 3, and s. albus with streptococcus in 2. The bacteria decreased and increased with the decrease or increase of the symptoms, and were so constant in occurrence that the author looks upon them as etiologically important.

An interesting discussion on rheumatism was held in the Section of Medicine of the British Medical Association,[3] which was opened by a paper read by Cheadle. The author reviewed very carefully the opinions which have been held regarding the nature and the relations of rheumatism in particular. Regarding the hereditary tendency, he found among 32 consecutive cases in private practice a definite history in 23, or 70%. If chorea and erythema be regarded as forms of rheumatism, there were 31 out of 33 cases, or 93%. If cases of arthritis, chorea, and heart disease be taken together, 180 cases gave 103 with a definite history, or 58%. If chorea (exclusive of grimacing) and heart disease are accepted as evidences of acute rheumatism, the proportion rises to 137, or 80%, with a definite family history. Double inheritance increases the tendency remarkably. After considering the different theories of etiology, he speaks at length of the infective theory, and points out the exact resemblance of rheumatism in its clinical course and complications with septic disease. The chief differences in the latter are the absence of chorea, the tendency to suppuration, the long continuance, and the lack of specific treatment. There are points which militate against the infective idea, such as the hereditary tendency, the absence of a fixed incubation period and of a definite course. These points, however, are by no means conclusive. The fact that the microorganism has not been discovered is another inconclusive point against the theory.

Of the complications, endocarditis is the most important. In 94 consecu-

[1] Wien. klin. Woch., No. xxvi., 1895. [2] Ibid., No. xxv., 1895.

[3] Brit. Med. Jour., Jan. 11, 1896.

tive cases, 62, or 66%, gave a definite history of rheumatic fever in the patient or immediate blood relations. If chorea and heart disease are accepted as evidences of a rheumatic taint, the percentage rises to 77. He believes that the cases occurring in connection with chorea are essentially rheumatic. Endocarditis is rheumatic in a great majority of the cases, and pericarditis almost exclusively. Tonsillitis occurs so frequently in direct and immediate association that the pathological connection is undoubted. It usually precedes, in rare instances it may follow after, the rheumatism. Erythema multiforme occurred in 4 out of 8 cases which were severe. With regard to erythema nodosum the evidence is equally as strong. Rheumatic purpura is closely associated with erythema. Further, he refers to hematuria and hemoglobinuria, and states that he has seen several cases of thrombosis of the vessels.

Regarding the connection of chorea, out of 55 cases in private practice there was history of rheumatic fever in the patients or blood relations in 27, or 52%. In 2 there was a history of chorea, in 2 of erythema nodosum and chorea, and in 1 of heart disease. Including these the percentage rises to 60%. Of the 55 cases, 10 were instances of face chorea or grimacing. If these are excluded, the proportion rises to 75%. Referring to the rheumatic manifestations in scarlatina, he states that either genuine acute rheumatism occurs or the poison of scarlet fever is capable of producing similar articular inflammation and choreic manifestations.

Dyce Duckworth in discussing the paper holds that a diathetic predisposition is necessary, and that this is distinctly hereditary. He views the disease as infective, and believes salicylates are useful because of their germicidal powers. The influence of the nervous system and local conditions determine the sites of the disease. The associated fever is a favorable condition, and checks the virulence of the bacillary cause.

Archibald Garrod points out that the temperature runs an indefinite course, and is greatly influenced by the local lesions. The clinical evidence points to the infective character of the disease, and chorea is probably the result of chemical poisons produced by the bacteria, just as post-diphtheritic paralysis is the result of such poisons.

Mantle suggested the infective nature of the disease several years ago. He cites an instance in which 5 cases of scarlatina occurred in one house, and arthritis was so marked that only the eruption made the diagnosis possible. Twice he saw acute rheumatism complicated by pericarditis followed by scarlatina in other members of the family in the same house. He has seen cardiac disease follow erythema nodosum; and in 1 case, in which the latter disease occurred in a child, the mother, who nursed it, contracted rheumatic fever. He dwelt upon the epidemicity, and states that he has seen 18 cases in a small village of 300 inhabitants in the course of 3 months.

Newsholme prefers the term rheumatic fever to acute rheumatism, as the latter implies the same cause for chronic rheumatism. He strongly supports the infective theory, and refers to the Milroy Lectures delivered by himself last year. He cites the epidemic occurrence in London prior to 1868 and

1874 and in 1884, and to the very marked prevalence in Christiania in 1864, in 1870, and in 1875.

Stewart of Edinburgh, while admitting the possibility of the infective theory, holds that all must agree that there is no absolute proof. He believes that the disease might originate locally, generally secondarily, a point with which MacKenzie could not place himself in accord. The latter held, as had nearly all of the speakers, that rheumatism is a systemic disease, and joint manifestations being local expressions.

Lees held that erythema nodosum is entirely independent of rheumatism.

Bannatyne, Wohlmann, and Blaxall[1] have examined 25 cases of rheumatoid joints, and in 24 found definite microorganisms which had peculiar properties of staining and growth, and were usually present in considerable, sometimes enormous, numbers. They believe that these microorganisms enter the system from some mucous membrane in a state of chronic inflammation (particularly the tonsils), and then, becoming located in the joints, give rise to poisonous products which pass into the body generally and act especially upon the nervous system. These bacterial poisons would seem to act by a hemolytic process which is specially limited in its action to the portal blood. Dr. Blaxall, for his part, reports that the organisms are very small, and that they stain with great difficulty and may be very easily decolorized. He has found organisms in all of 18 cases of rheumatoid arthritis, but never in chronic joint diseases of other origin. He has also found the organisms in the blood of 3 out of 5 cases. The organism itself is a minute bacillus, exhibiting marked polar staining.

Gerhardt[2] at the Congress for Internal Medicine contributed a paper upon rheumatism and rheumatoid diseases. He holds that the nature of rheumatism is still an open question, no uniform infectious cause having been discovered. He classifies as impure forms of rheumatism the joint manifestations of the various acute exanthems—typhoid fever, dysentery, gonorrhea, purpura, and similar affections. In these there may be no fever or there may be considerable. The specific organisms of the infectious fevers seem to be the cause of the joint troubles, acting by metastasis. Regarding the reputed want of activity of the salicylates, he points out that this is true also of notable numbers of cases of true rheumatism. Regarding the occurrence of angina with rheumatism, he states that this was noticed in 21 % of the cases in his clinic. The angina was usually slight. He calls attention to the fact that bacteria are commonly found on the tonsils, and that the same sort are there present as have been found in the joints of rheumatism. It may be doubted, however, whether the bacteria are carried to the joints, since it is possible that toxic substances may be so conveyed and may be active.

Wade[3] considers the microbic origin of rheumatism and its connection with tonsillitis. He notes that it is a prominent circumstance that tonsillitis usually

[1] Lancet, Apr. 25, 1896.

[2] Centralbl. f. innere Med., Apr. 25, 1896; Berl. klin. Woch., Apr. 20–27, 1896.

[3] Brit. Med. Jour., Apr. 4, 1896.

precedes the rheumatic fever, while, on the other hand, occasionally the rheumatism precedes the tonsillitis. He points out that tonsillitis in its clinical manifestations corresponds with other infectious diseases, that undoubted contagion has occurred, and that various forms of microorganisms are found within the crypts while these are surrounded by aggregations of leukocytes. Further, it is striking that acute rheumatism resembles the infectious diseases and is probably infectious in its nature. Referring to cases of tonsillitis in which rheumatism has not followed or cases in which repeated attacks have occurred and rheumatism has not developed until the last, he suggests that it is likely that there is a special bacterial cause of rheumatism whose entrance into the tonsils or multiplication in the tonsils is favored by the existence of tonsillitis. The presence of this organism is necessary to development of the disease.

Williams [1] reports a case of articular rheumatism with, later, acute left-sided pneumonia, developing subsequently to extensive tatooing of the left forearm. Later chorea also developed, involving at first the left, but later both sides, and the heart was found to be affected. [The case is of interest in connection with the etiology of the disease, and would seem to indicate the possibility of external infection in some cases.]

Symptoms.—Fuchter [2] records 9 cases of rheumatism with altered cardiac or other disease in which subcutaneous nodules appeared, such as have been described by Jaccoud, and particularly by Barlow and Warner. In considering the lesions which resembled the rheumatic nodules the author notes the following: Traumatic subcutaneous nodules, in which, however, the number is limited; the epithelial nodosities of Ferreol, in which the true skin is involved and the nodules are less hard; erythema nodosum, in which, however, the size is much greater and the skin presents evidences of inflammatory change; subcutaneous gummata, in which the skin is usually adherent and evidences of inflammation or of general syphilitic infection are abundant; tophi; urticarial wheals; Heberden's nodosities; subcutaneous syphilitic nodules other than gummata, in which the history alone and the absence of signs of rheumatism would make the diagnosis of fibroid nodules, nodules of osteoarthritis, and certain benign growths such as lipoma and fibroma. The fibromata are, however, difficult to distinguish, as the rheumatic nodules are in reality fibromatous. Histologically, he found bundles of fibrous tissue and cellular elements, small round cells, fibroblasts, and polynuclear leukocytes. In the cellular process the blood-vessels were quite abundant.

Treatment.—Pearse [3] reports 14 cases of acute rheumatism treated with salophen. In 12 of these the temperature was certainly produced by the rheumatic condition, and the average duration of fever after beginning to use salophen was 5 days. The average daily dose was $1\frac{1}{2}$ drachms. There were no symptoms of cardiac disturbance or renal or cerebral involvement.

Henry [4] in a note on the treatment of rheumatism with salicyl compounds

[1] Brit. Med. Jour., No. 1800, 1895.
[2] Johns Hopkins Hosp. Bull., Sept. and Oct., 1895.
[3] N. Y. Med. Jour., Mar. 14, 1896.
[4] Phila. Hosp. Rep., vol. iii., 1896, p. 45.

states that he employed them in 1877 in a large series of cases at the suggestion of his interne, Dr. C. B. Goldborough. This was the first employment of this treatment, as far as the author knows, in hospital practice in Philadelphia or perhaps even in America. The administration of salicylic acid showed a wonderful contrast to the previous results with the old alkaline treatment. H. notes the tendency to return to the use of the pure acid manifested of late, and regards this retrograde step as a wise one, the pure acid in his experience being more efficacious than any of its compounds.

Weiss[1] has studied the effect of serum injections in 10 cases of articular rheumatism. The serum was obtained from patients who had recently recovered from acute rheumatism of typical character. The author does not believe it possible to draw absolute conclusions from these cases, because, though some showed remarkable improvement after a single injection, others were injected several times without apparent effect, and salicylates had to be given in the end. In all 22 injections were given. The local disease was apparently influenced in 9 cases. As far as the general condition was concerned, 6 manifested no change.

Gonorrheal Rheumatism.—Hawkins[2] reports the case of a young man who acquired acute gonorrhea. Subsequently gonorrheal rheumatism developed; he became delirious, had high temperature, and toward the end became comatose. The antemortem temperature reached 105.6° and the pulse 170°. There were no convulsive movements, no paralysis, and no abscesses. The urine was not examined, and there was no autopsy.

DERMATOMYOSITIS.

[The relations of this condition to rheumatism remain unsettled. Undoubtedly they are allied and the evidence that dermatomyositis is infectious is quite strong. Various microorganisms have been discovered, and it is likely that infections of quite different sorts may tend to similar clinical manifestations.]

Pfeiffer[3] contributes an interesting review of polymyositis or dermatomyositis acuta. The symptomatology of the cases described under this name varies very much. The disease begins suddenly or gradually, and sometimes with general symptoms, such as headache, weakness, dizziness, and disturbances of the stomach. Moderate fever with rapid pulse and enlargement of the spleen occur, and local symptoms—edema and eruptions of the skin, inflammation and tenderness of the muscles—are characteristic conditions. Hard areas of infiltration or softening may occur in the muscles, the disease usually affecting the extremities first and then the trunk. Muscles of the eye, tongue, heart, and diaphragm are rarely involved. The most characteristic eruption is one resembling urticaria, but more persistent and having a deep red color. Subcutaneous edema may be excessive. The nervous system is not involved. The joints are unaffected and the urine free from albumin. The course is

[1] Centralbl. f. innere Med., Apr. 25, 1896. [2] Med. News, June 13, 1896.
[3] Centralbl. f. Allg. Path. und Pathol. Anat.

indefinite; complete recovery may occur after a brief or long attack, sometimes leaving atrophies with altered electrical reactions of the muscles. In severe cases death may occur from implication of the muscles of respiration and swallowing. Among the reported cases differences are noted in the character of the eruption and other symptoms. The cause is evidently some infectious principle, and Pfeiffer believes the disease to be identical with the myositis gregarinosa of the lower animals. The differential diagnosis from trichinosis is difficult, and can only be made after careful examination of parts of excised muscle and a study of the history of the case. In neuromyositis the tenderness of the nerve trunks and altered sensation make the diagnosis. The myositis of sepsis, syphilis, typhoid fever, alcohol, or overexertion is recognized by the history. The author concludes as follows: 1st. The combination of lesions of the skin and inflammation of the muscles is not sufficient upon which to base a diagnosis; 2d. The diagnosis is easy if the type as presented by Unverricht is accepted; 3d. The existence of chronic forms requires further confirmation; 4th. The cause is uncertain, but an infectious agent is most likely; 5th. Careful clinical, bacteriological, and histological studies are still necessary.

Herrick [1] contributes a most interesting review of **polymyositis acuta** and reports a case of his own. The disease, which has also been known by the names dermatomyositis and pseudotrichinosis, is characterized by inflammatory swelling of the muscles, eruptions of the skin, enlargement of the spleen, and finally inflammation of the muscles of deglutition and respiration, leading to death. Atypical and mild cases have been observed. Trichinosis, polyneuritis, and syphilis attacking the muscles must be excluded. The cause is still unknown, but microorganisms, chemical poisons (toxins), and animal parasites (gregarina) are suspected. Exclusion of trichinæ can only be made by repeated examinations of portions of excised muscle. Syphilitic myositis usually occurs late, appears without exciting cause, affects no particular muscle, and may involve more than one. It may occur as a gummous or diffuse form or as a combination of the two.

The author's case was a woman of 24, whose previous history had furnished no important indications. Subsequently it was learned that she had suffered with sore mouth and throat for a full month some ten years before, and a year later small painless swellings had appeared on the tibiæ. Her husband had been on antispecific treatment and she herself had enlarged lymphatic glands. The disease began with sharp pains in the forearm, followed by swelling and tenderness. Two days later the calf of the right leg was similarly affected, and three weeks later the other leg was involved. There was no enlargement of the spleen or liver, and examination of the blood showed moderate reduction in the number of corpuscles and in the hemoglobin, with slight increase in the polynuclear leukocytes. The temperature was moderately febrile. Incision was made into one of the muscles and portions removed. A light brownish-red fluid escaped, and some fragments of old clot. Cultures were negative. Microscopically extensive diffuse inflamma-

[1] Am. Jour. Med. Sci., Apr., 1896.

tory changes were found in the muscle. The fibers varied in size and presented a hyaline appearance. Nuclear proliferation and mitotic figures were abundant. Extravasation of leukocytes between the fibers was marked, especially about the vessels.

Zahradnicky[1] describes a case of purulent post-typhoid myositis. The abscess occurred in the muscles of the chest wall beneath the right clavicle, forming a broad flat swelling. Incision was made and 50 cc. of pus were evacuated. Cultures made from these showed the presence of the typhoid bacillus without other organisms. The author points out that post-typhoid suppuration may be due to mixed infections of typhoid bacilli and pyogenic microorganisms, to secondary infection, or to infection with the typhoid bacillus alone. His own case is of the latter description.

RHEUMATOID ARTHRITIS.

Armstrong[2] believes in the dystrophic theory of rheumatoid arthritis, and divides the joint changes into six classes, according to their cause: rheumatic, gouty, uteroovarian, phthisical and strumous, neurotic, and local. The most valuable treatment is found to be constant and alternating galvanic baths with wine of cod-liver oil. The results of this treatment are increase in strength and general improvement, with greater power of movement. Seclusion and rest are also of much service. Massage and hot baths are apt to do harm. He recommends Aix-le-bains, Buxton, and other well known baths. [It seems unnecessary to adopt elaborate classifications of causes such as the above. The essential underlying cause is still obscure, and complex classifications do not relieve the obscurity. Nervous depression undoubtedly plays a part in the genesis of this disease, and may arise in a multitude of ways.]

Fox[3] classifies rheumatoid arthritis under three heads: the arthritis of the young, the most severe and intractable form; generalized rheumatoid arthritis of the climacteric epoch, limited to females; and senile rheumatic arthritis, affecting chiefly males, this form belonging to the degenerative period and being frequently preceded by nervous depression. There is very strong evidence that some implication of the nervous system is the essential cause, and therefore the disease may be looked upon as a neurosis of which the principal manifestation is found in the joints.

Brabazon[4] analyzes 100 cases of rheumatoid arthritis. Of these 3 were typical and occurred in children between the ages of 5 and 15 years. Pigmentation spots were noted in 19 cases, and he regards them as valuable aids to diagnosis, although their absence does not exclude the disease. He describes a characteristic facies which consists of a worn and anxious expression, indicative of both mental and physical suffering, particularly in females. He considers the disease a disordered condition of the trophic nerves, producing atrophic conditions of the intraarticular structures, and involving, in a general

[1] Wien. klin. Rundschau, No. 43, 1895.
[2] Brit. Med. Jour., May 16, 1896.
[3] Internat. Med. Mag., Sept., 1895.
[4] Brit. Med. Jour., Mar. 21, 1896.

way, the muscular and other structures of the body, accompanied by a series of constitutional symptoms.

Reynolds [1] points out the distinguishing features in the deformities of the hands produced by gout and those resulting from chronic rheumatic diseases, including among the latter rheumatoid arthritis and the changes following acute rheumatism. The distinguishing point is that in gout the affection of the hands is markedly asymmetrical on the two sides, and the deformities may be quite different; while in the other conditions symmetrical involvement is the rule.

LITHEMIA.

Pathogenesis.—[The generic term lithemia may be employed to designate the systemic manifestations resulting from excess of uric acid or the allied bodies—the alloxins. The formation of these substances, and particularly their derivation from the leukocytes, has been studied with great zeal by the physiologic chemists, and practical applications of the knowledge thus acquired will doubtless soon follow. Further references are made in the sections on Diseases of the Blood, in the article on Gout, and elsewhere.]

Kossel [2] holds that the products of cellular destruction may be divided into (1) the xanthin bases (xanthin and guanin); (2) the sarcinin bases (hypoxanthin and adenin); (3) cytosin. These substances result from the destruction of nuclein and nucleinic acid. This explains the frequency of the bases named in the blood of leukemia, where they result from destruction of the leukocytes. The increased quantity of uric acid in the urine is evidence of cellular destruction. A part of the nuclein cells does not produce nuclein bases. Kossel separates this part under the name of paranuclein, and places the phosphorus-containing bodies of milk and yolks of eggs in this group.

Zuelzer [3] denies the statement of Kolisch that the conversion of xanthin bases into uric acid occurs in the kidneys and is dependent upon healthy renal functions. Unlike Kolisch, he found the ratio of uric acid to xanthin bodies little altered in nephritis, the uric acid being considerable in quantity in cases of nephritis, while the xanthin bases were not increased.

Brandenberg [4] has studied the diagnostic significance of uric acid and the xanthin bases on the urine. He finds that the alloxins increase proportionately to the total nitrogen when there is increase in the amount of food ingested, and that they decrease when nitrogenous elements are withheld, whether there be sufficient caloric units in the food or not.

In case of infection, however, when there is increased destruction of bodies containing nuclein, such as occurs in typhoid fever, the nitrogen of the alloxins reaches an abnormally high figure. In cases of carcinoma and other cachectic conditions it was found that the amount of nitrogen excreted was considerably in excess of that ingested, and he concludes that it indicates a very considerable loss of albumin from the body itself, and that whenever we find a remark-

[1] Brit. Med. Jour., Feb. 15, 1896.
[2] Berl. klin. Woch., Jan. 27, 1896.
[3] Centralbl. f. innere Med., Apr. 25, 1896.
[4] Ibid., No. 7, 1896.

ably rich excretion of the alloxin bodies in the urine, so that the relations between these and the total nitrogen are disturbed, suspicion should be aroused that the disease is one of malignant character. In those cases in which the uric acid was diminished in the urine the amount of the alloxin bodies found in the feces was lessened, and it appeared increased in those conditions, such as leukemia, in which there is an excessive excretion of uric acid.

When substances rich in nuclein, such as calves' thymus, was introduced into the alimentary tract, the amount of uric acid in the urine was always greatly increased, being, in a case of secondary anemia, almost double.

Weinstraud [1] claims that uric acid is produced in the intestinal tract in considerable quantity. This is an actual secretion, and not a mere elimination of uric acid nor a remnant from the ingested food, as the existence of uric acid in the meconium or intestinal tract after a diet free of nitrogen would indicate.

Symptoms.—Norbury [2] speaks of the importance of lithemia in the causation of various mental symptoms, such as a moody condition and explosive irritability, and other symptoms of neurasthenia. He reports 2 cases in which treatment directed to the lithemic condition completely cured these manifestations.

Rachford [3] discusses poisoning by leukomains of the uric-acid group, and recognizes four distinct types: leukomain-headache, epilepsy, gastroneuroses, and asthma. He reports a number of cases in which various forms of leukomain-poisoning occurred produced by such conditions as gout, chronic alcoholism, lead-poisoning, and uremia. In all of these cases, during the height of the attack, considerable paraxanthin was found in the urine, which produced characteristic toxic symptoms in mice.

Treatment.—Bohland [4] has investigated the action of **salicylate of soda** upon the excretion of uric acid. He finds the latter noticeably increased, and there is at the same time considerable increase of the leukocytes in the blood, so that there is therefore increased excretion of uric acid. This excretion is particularly owing to the destruction of the leukocytes, and he therefore concludes that the remedy is not to be recommended in gout, not even as a temporary analgesic.

Hills [5] reports his experiments upon uric acid in a number of cases, among others that of a patient subject to attacks of sick headache. During one of these attacks the ratio of uric acid to urea was 1 to 23. After the administration of salicylate of sodium the ratio fell from 1 to 15, but gradually increased again. Some days after the salicylate was stopped he had another attack of headache, in which the ratio was 1 to 50. In this case Hills concludes that the salicylate cleared the system of uric acid, and that the fact that headache could occur when the system was thus clear proves that the uric acid is the result and not a cause of the condition.

In a case of diabetes mellitus when there was considerable sugar the ratio

[1] Centralbl. f. innere Med., Apr. 25, 1896. [2] N. Y. Med. Jour., June 27, 1896.
[3] Med. News, May 16, 1896. [4] Centralbl. f. innere Med., Jan. 18, 1896.
[5] Boston M. and S. Jour., Mar. 19, 1896.

varied from 1 : 22 to 1 : 14. When the sugar disappeared it was practically the same, varying between 1 : 21 and 1 : 15. In the case of a man suffering from asthma in the interval the ratio was 1 : 36, during the attack 1 : 41.6.

In conclusion Hills argues that the purely chemical theory of Haig cannot be accepted as proved, and that it is very probable that the symptoms of uric-acidemia are not produced by uric acid, but rather by a perverted nutritional state, possibly of nervous origin, which results in an altered cellular metabolism.

Rachford[1] advocates the following treatment for conditions in which **leukomain-poisoning** due to paraxanthin or other bodies of the uric-acid group is supposed to be present. Potassium permanganate is administered in pill form, each pill containing 1 grain and being coated with salol: 3 of these are administered daily an hour after meals, and 1 teaspoonful of mixture in a glass of seltzer water each morning, sodium salicylate 2 drams, dry sodium phosphate 4 drams, dry sodium sulphate 10 drams. Among the cases which he records as instances of leukomain-poisoning are migraine, migrainous epilepsy, and certain gastric neuroses.

GOUT.

Etiology.—Kolisch[2] constructs **a striking theory** regarding the pathology of gout. According to this theory the essential pathology of gout consists of the increased destruction of nucleins, especially those found in the leukocytes with a production of alloxins. The latter, instead of being transformed into uric acid in the organs having this function (notably the kidneys), circulate and constitute the poison of gout. The condition of the kidneys, therefore, is of prime importance in this disease, and dietary habits, modes of life, and alcoholic or plumbic intoxication manifest themselves by their influence upon the kidneys primarily, and secondarily upon the other organs which transform the alloxins. The hereditary basis underlies the tendency to continuous excess of nucleinic reduction.

Pfeiffer[3] has carefully studied 14 cases of gout, during both the latent period and the crisis, in regard to the excretion of **urea and uric acid.** He finds that in the latent periods the average daily quantity of urine is 22.8%, higher than the normal, but the specific gravity and the acidity are reduced more than a half. The total uric acid averages 0.6 g. per day, and the total urea 19.25 g. per day, both excessively low numbers. The relation of the urea and the uric acid is as 31.8 : 1, whilst in normal individuals it varies from 35 : 1, to 40 : 1. In the majority of cases uric acid existed in the free state. During the crisis, however, it is found that not only is the daily quantity of urine not invariably diminished, but that the specific gravity is increased, and there is also a marked increase both in the amount of uric acid, which reached nearly 1 g., and the amount of urea, which reaches an average of nearly 31 g. a day, with a ratio between the two of 31.6 : 1. The majority of the cases showed the completely combined uric acid during the attack.

[1] Med. News, Dec. 7, 1895.
[2] Wien. klin. Woch., No. 45, 1895.
[3] Berl. klin. Woch., Apr. 13, 1896.

Pfeiffer undertook some experiments to test the pain-producing effect of uric acid. He found that injections of emulsions of the insoluble forms are practically painless, but that as soon as a soluble salt was employed intense pain was produced. He concluded from this, and also from the fact that a free use of alkalies frequently produces a gouty crisis, that it is not improbable that the pain of the crisis is due to increased solubility of the urates of sodium in the system, and that the conditions for the production of the crisis are therefore increased alkalinity of the juices of the body. In regard to the excretion of phosphoric acid, although in a few cases it was increased during the crisis, it is impossible to draw any definite conclusions.

Saturnine Gout.—Packard [1] contributes some interesting observations on the relation of lead-poisoning to gout. He studied some 50 workers at one of the large manufactories, and bases his observations upon the facts so obtained. Among the 50 cases there was none in which signs of tophi in the ears or eyelids were discovered, and only 1 case of articular gout. This case, a man of 40, a drinker of beer and porter, had been steadily employed for 13 years in washing the crocks used in the tan-room. The signs of gout consisted in thickening of the articular ends of the bones of the hand. These thickenings were entirely quiescent, and the patient attributed them to traumatism in handling the crocks. There was no other evidence of gout. The statistics collected by the author showed a marked predominance of gout in England as compared with America, while the cases of lead-poisoning are rather more numerous in America (Philadelphia) than in England. The author concludes: "In America, and at least in Philadelphia, plumbism is by no means rare, showing itself more commonly as wrist-drop or colic; less commonly as encephalopathies; still less as arthralgias; and with extreme rarity as gout."

Luethje [2] has investigated the subject of lead-gout and uric-acid excretion in chronic lead-poisoning. There does not seem to be any doubt of the close relationship between lead-poisoning and gout; and lead alone may cause it. Plumbism has no special effect on the excretion of uric acid, but leads to overproduction and consequent surcharge of the blood. Attacks of gout occur only after long-continued poisoning, and, as a rule, in early life. The affection spreads rapidly over many joints, and not rarely affects the hips, vertebræ, and shoulders, which are only exceptionally affected in ordinary gout.

Widal [3] reports the case of a patient suffering from chronic saturnism, with intense acute pain in the metatarsophalangeal articulation of the left foot. Later, pericardial effusion developed and the patient died. At the autopsy a huge purulent pericardiac effusion was found lying posterior to the heart, the pericardium being bound down anteriorly by adhesions. This liquid was found to contain pure cultures of pneumococci, and the same organisms were found in the swollen joints, together with an abundance of crystals of sodium urate which probably anteceded the infection and acted as a predisposing cause.

[1] Phila. Hosp. Rep., vol. iii., 1896, p. 29. [2] Zeit. f. klin. Med., Bd. 29, p. 266.
[3] Gaz. Hebdom. de Méd. et de Chir., Jan. 30, 1896.

Symptoms.—Magnus-Levy[1] reports a case of gout in which, 14 days after the commencement of the attack, there was an enormous excretion of nitrogen with improvement. The quantity of nitrogen excreted gradually diminished, and finally became very slight. In a second attack there was again a difference, but not nearly so marked. Ammonia was present in very small quantities. He refers to the average daily quantity of the various nitrogenous constituents of the urine in 9 cases, in which only 2 showed considerable increase of the alloxin bodies, and warns against positive conclusions from these results.

Treatment.—Kolisch[2] bases his views of the treatment of gout upon his theory of its pathology. Every influence which may lead to irritation or injury of the kidneys must be eliminated, and in particular alcohol and diet, which might increase the amount of irritating alloxins, must be interdicted. Among the latter are flesh rich in cellular constituents, while muscle, particularly such as has been boiled, is permissible. The carbohydrates and fats may be allowed. Milk and eggs are entirely unobjectionable, as the nucleins contained do not form alloxins. Of the vegetables, salads and greens, excepting such as asparagus, are useful. Over-exercise should be avoided on account of the tendency to increase the alloxin productions. [Kolisch's theory is attractive, but wants confirmation, and is opposed by a number of facts. The evidence in favor of the view that the final transformation of the alloxins occurs in the kidneys is scanty, and contradictory reports might be cited. Upon the whole, it seems unlikely that the renal activity is as important as Kolisch believes.]

Sir Alfred Garrod[3] in a paper on the use of **guaiacum** in gout states that 1. Guaiacum is innocuous, and may be taken indefinitely like ginger or other condiments; 2. It has power (but less than colchicum) to relieve acute attacks, being specially useful when there is little fever; 3. It is a powerful prophylactic when given between attacks; 4. Long use does not cause a loss of this prophylactic power; 5. Some persons cannot readily take the drug.

Fawcett[4] finds that piperazin is useless as a remedy for gout, as it gives no relief of pain nor increase of uric-acid excretion.

DIABETES.

Etiology.—[Nothing of great significance has been added to the knowledge of the etiology or pathogenesis of the disease. The most important contribution, that of Klemperer, is designed to establish a new element, that of renal derangement. The clinical evidence of this is entirely insufficient, as the gentlemen participating in the discussion of the paper pointed out, and the experimental evidence based upon the administration of phloridzin has not been sustained by others (Magnus-Levy) who have followed Klemperer's method. It seems improbable that the condition of the kidneys is of great importance.]

[1] Berl. klin. Woch., May 4, 1896. [2] Loc. cit.
[3] Brit. Med. Jour., May 30, 1896. [4] Guy's Hosp. Rep., London, Perry & Jacobson, 1895.

Klemperer[1] in a paper before the Berlin Society for Internal Medicine, referred to the relations of renal conditions to glycosuria. He first called attention to the fact that numerous observers, particularly among the English, had noted the disappearance of diabetes in individuals who had developed nephritis. He himself had observed such cases. It would seem, therefore, that the kidney-cells in themselves exercise some regulating function in regard to the excretion of glycogen. Further, he referred to experimental phloridzin-diabetes, which distinguishes itself from all other varieties by the fact that the blood does not contain excess of glycogen; on the contrary, it would seem that the renal irritation occasions the glycosuria, since the extirpation of the kidneys in such cases does not increase the glycogen in the blood, and the injection of the poison into one of the renal arteries causes excretion of glycogen from that kidney alone. Further, in his own experiments he found that phloridzin did not produce increase of glycogen in the blood of men despite the occurrence of glycosuria, and in 10 cases of chronic interstitial nephritis in which he administered this substance, 7 did not develop glycosuria. Phloridzin differs from other substances which produce glycosuria in another particular, the excretion of glycogen in the case of other glycosuria-producing substances being dependent upon the consumption of carbohydrates. **Renal diabetes,** in the sense in which the author understands it, is very rare, but he believes it can be recognized, and he refers to an instance affecting a man of 50 years with striking evidences of intravascular hypertension and albuminuria. He had formerly suffered with marked diabetes, but at the time had only slight glycosuria. Despite the administration of excess of various carbohydrates, the quantity of sugar in the urine remained unaltered, and the same was true of pure meat diet. In the discussion which followed upon this paper Fränkel, Gerhardt, and others held that the author's views must be taken as hypothetical and unproved for the present.

Oppler and Külz[2] discuss very fully the occurrence of **diabetes mellitus in married couples** with reference to the question whether the disease is contagious by means of the genito-urinary tract or not. They collect a number of interesting cases in literature, and finally analyze 900 cases of diabetes that had been observed in the practice of Professor Külz. Among these 900 cases were 9 married couples. In all of the cases careful investigation of the urine was repeatedly made in order that there should be no question about the diagnosis. Regarding the statistics of the condition, they collect, with their own, 4389 cases of diabetes, among which were 47 married couples. After carefully discussing the etiology of their various cases, they decide that in no case is it necessary to accept the occurrence of infection to explain the origin of the disease, and therefore it is unlikely that infection occurs.

N. S. Davis[3] in a statistical paper on diabetes mellitus calls attention to the fact that in cases under his observation during **certain months** sugar appeared in the urine with less regularity than in other months. Analyzing 55

[1] Centralbl. f. innere Med., June 13, 1896. [2] Berl. klin. Woch., June 29, 1896.
[3] Am. Jour. Med. Sci., July, 1895.

cases, he found glycosuria 3 times as often in March and in April as in June, 4 times as often in July, and a little more than 3 times as often in November. It occurred less frequently in December, January, and February, and was notably less common in May than in April or July. Stating the proportion of positive results of examination for sugar to the negative results during the same months, he finds as follows:

January	51%.	July	44%.
February	38 "	August	38 "
March	51 "	September	44 "
April	30 "	October	47 "
May	47 "	November	38 "
June	34 "	December	43 "

Lépine [1] concludes that diabetes is increasing in Paris, where alcohol acts as an important predisposing factor, but that it does not appear to act in this manner in India. He doubts the statistics that have been published regarding the distribution of diabetes.

Whitton [2] relates a family history in which the father died of diabetes at the age of 65. One son developed epilepsy, and of 3 children of his daughter, 1 had hare-lip, 1 was an epileptic, and 1 had facial paralysis. One son had a daughter with 6 fingers and 6 toes on each hand and foot. Another case developed diabetes at the age of 50. A grandson was idiotic in consequence of early closure of the cranial sutures.

[The occurrence of **glycosuria in various infectious diseases** is well known. Among others pertussis and influenza have been frequently mentioned. In most instances these cases are mild and transient; occasionally, however, severe cases are recorded.] Duke [3] reports a case of diabetes occurring in a girl 13 years of age after an attack of measles. Sugar was present at the majority of examinations, at one time amounting to 12 grains per ounce. The most effective treatment seemed to be that with codein. Bohling [4] was called to a patient who had previously suffered from nothing more than a slight attack of influenza, and was apparently in good health. He found the patient in a state of coma, from which he did not recover. The urine contained sugar and considerable acetone. There had previously been neither polyuria nor excess of appetite or thirst.

Obici [5] reviews the literature bearing on the **relation of pancreatic lesions to diabetes.** He warns against the view, sometimes entertained, that all cases of advanced diabetes are dependent upon pancreatic lesions. The relation has by no means been determined. The course of the disease in cases in which the pancreas is affected often varies. He reports 2 cases of equally rapid diabetes with equal amounts of sugar, in 1 of which the pancreas was affected, and in the other healthy. He also details 2 cases of interstitial pancreatitis and 1 of carcinoma with complete destruction of the gland, in all of which

[1] Rev. de Méd., Dec. 10, 1895.
[2] New Zealand Med. Jour., Jan. 1, 1896.

[4] Brit. Med. Jour., Feb., 1896.
[5] Boll. del. Sc. Med. di Bologna, Series 7, vol. iv.

there was no sugar in the urine. In the first of the cases the interstitial pancreatitis was of vascular and lymphatic origin, representing the changes which Lépine regards as particularly favorable to the development of glycosuria.

Triboulet[1] urges that certain forms of diabetes are unquestionably associated with alterations of the liver. Particularly is this true of alcoholic diabetes associated with hepatic cirrhosis.

Symptoms.—Thayer[2] reports several cases of diabetes which were remarkable for the small quantity of urine passed. One is said to have passed 9 oz. of urine and 3¼ oz. of sugar in 24 hours; in another 7 oz. of urine and 2½ oz. of sugar. In the others the proportions were about the same. He claims to have cured a patient by an exclusive meat and salad diet. [We have repeatedly met with cases in which the quantity of urine was small and the amount of sugar excessive. The figures in the above report, however, are remarkable.]

James[3] has examined the blood in 2 cases of diabetes. He finds that when fasting from both food and drink there was a condition of anhydremia, the corpuscles being considerably above 6,000,000 and the hemoglobin 100%. After drinking copiously of water the number of corpuscles, the amount of hemoglobin, and the specific gravity of the blood decreased.

Complications.—Bussenius[4] reports, from Senator's clinic, a case of **lobar pneumonia** occurring in a patient who had diabetes. The sugar did not disappear from the urine, but was present in large quantities, despite the fact that only small amounts of carbohydrate food were given by the mouth. With the beginning of the fatal termination the amount increased rapidly, but later it diminished so that hardly a trace was found just before death: 0.25% of sugar was present in the patient's sputum. Among 700 cases of diabetes seen by Senator, there were 7 instances of pleuropneumonia with 4 deaths. In these cases the sugar never disappeared entirely, though in 1 there was notable decrease.

Kœnig[5] reports 2 cases of **gangrene** occurring in diabetes in which, after failure of dietetic treatment, amputation was practised, with prompt recovery from the operation and subsequent disappearance of sugar from the urine.

Nonne[6] reports the case of a woman aged 64 who had moderate diabetes, and 4 years later gradually developed progressive **muscular atrophy,** beginning in the upper limb, extending to the lower, and being accompanied by reactions of degeneration. She died of bronchopneumonia. Microscopic examination of the cord showed chronic degeneration of the cells and fibers in the anterior horns from the cervical to the lumbar regions. The author believes this to be the first case in which typical signs or progressive muscular atrophy have been found during life in diabetes, and in which the lesions were found postmortem.

Pigmentary Diabetes.—Marie[7] records a case of *diabète bronzé*, and

[1] Gaz. Hebdom. de Méd. et de Chir., Apr. 19, 1896.
[2] Med. Rec., Aug. 17, 1895.
[3] Edin. Med.Joul., Apr., 1896.
[4] Berl. klin. Woch., Apr. 6, 1896.
[5] Ibid., June 22, 1896.
[6] Ibid., Mar. 9, 1896.
[7] Semaine méd., 1895, p. 229.

summarizes the literature of this interesting affection. He asserts that in 11 cases he found recorded all presented much the same symptoms. It occurs in adult life, and especially in men, and alcohol is the important cause. Dryness of the mouth, excessive thirst, polyuria, and diarrhea are early symptoms. The amount of sugar in the urine varies in different cases and at different times, but is usually small and diminishes toward the end of the disease. Tympany, slight ascites, enlargement and tenderness of the liver, enlargement of the spleen, and distention of the abdominal veins are the ordinary abdominal symptoms. Sometimes there is lymphangitis of the skin of the abdomen. The skin is mildly jaundiced and the urine dark, but probably not from bile. Rapid emaciation and edema of the lower extremities supervene. The pigmentation of the skin involves the whole body, though it is darker on the exposed parts and about the genitalia. The mucous membranes are unaffected. The color of the skin varies from a brown to a grayish black. The disease is rapid, and death usually occurs within a year, preceded by increased edema, and sometimes by high fever or a purpuric eruption. The sugar may disappear entirely from the urine.

Marie's patient was a man of 51, who began to drink heavily at 40, and had severe bronchitis. Six years later an abscess formed on the arm and discharged offensive pus; 4 years later he had grip, followed by edema of the legs and gradually increasing evidences of pigmentary hepatic cirrhosis with glycosuria. He finally died of tuberculosis of the lungs. Postmortem the liver was found dark, enlarged, and cirrhotic, and there was more or less sclerosis with pigmentation of the pancreas and the heart as well. This pigment of the liver and other organs was iron-containing, and responded to the reaction with ammonium sulphid. The pigment is derived from the hemoglobin, which is liberated under the influence of some primitive cause, and then transformed in the cellular protoplasm of the organs. Marie insists that this is a specific disease, having some resemblance to pancreatic diabetes, and not a variety either of hypertrophic cirrhosis with pigmentation nor of ordinary diabetes.

Hanot,[1] referring to the form of diabetes accompanied by hepatic cirrhosis and pigmentation of the skin, first described by himself in collaboration with Chauffard in 1882 and afterward (1886) called *diabète bronzé* by himself, holds with Marie that this is an independent disease or entity. The hepatic cirrhosis is a vascular and generally hypertrophic condition, the liver in different cases weighing from 1800 to 3500 g. The important symptoms are those of diabetes, with abundant glycosuria, melanodermia, most marked upon face, limbs, and genitals, general symptoms of hypertrophic cirrhosis, with enlargement of the liver and spleen, slight ascites, and distention of the abdominal cutaneous veins. The author refers to 2 cases recently under his observation.

Diagnosis.—Bremer[2] has contrived a reagent which consists of a mixture of a saturated watery solution of eosin and methylen blue, from which the precipitate is filtered, dried, and reduced to a fine powder. To this is

[1] Brit. Med. Jour., Jan. 25, 1896.

[2] N. Y. Med. Jour., Mar. 7, 1896.

added small quantities of eosin and methylene-blue. If now diabetic blood be fixed upon cover-glasses by means of heated alcohol and ether and stained with this reagent, the erythrocytes acquire a deep green color which is totally different from the color of normal erythrocytes. This color, he holds, is due to some foreign body in the corpuscles, which is certainly not glucose, and is not dependent upon the amount of sugar which appears in the urine. It occurs in all forms of diabetes and glycosuria, excepting those produced by phloridzin. From a single case in which it did not occur Bremer believes that it is not characteristic of glycosuria, which is essentially renal. It is therefore of value in differentiating hematogenous glycosuria from renal diabetes. [We cannot agree with the author's views, as we have occasionally found the same green color in staining the blood of various diseases with eosin and methyl-blue. Sometimes the results obtained have been exactly those described by Bremer. We must therefore regard the test as valueless.]

Treatment.—Robin[1] employs a form of "**alternating treatment**" in diabetes. He believes that the increased chemical changes, and those of the liver particularly, result from stimulation of the nervous system, and therefore recommends drugs which act upon this system primarily. For 4 days he administers 15 gr. of antipyrin and 8 gr. of sodium bicarbonate twice daily, while cod-liver oil is taken twice a day and Seignette salt as a purgative in the morning. At the end of 4 days he gives 6 gr. of quinin after the midday meal, continuing this for 6 days, then discontinuing 4 days, and again administering for 6. Before the morning and evening meals a capsule containing arseniate of sodium, carbonate of lithium, and codein are recommended. Next he gives a pill of opium, belladonna, and valerian for 10 days, and the patient is allowed to drink a weak solution of bicarbonate of soda (1 : 125). In nervous women or when there is intolerance of the opium and belladonna potassium bromid may be substituted. Further, he recommends the food to be well salted, and advises the green vegetables and also a weak solution of potassium tartrate to supply the needed potash, with glycerophosphate of lime and magnesium to supply the phosphates. He has used this "alternating method" in 100 cases, in each of which the daily amount of sugar excreted was 100 g. or more. In 24 of these recovery occurred, in 25 recovery is still doubtful, in 33 there was improvement, and in 18 the results were negative.

Cassaet[2] advocates the use of **brewer's yeast** in all forms of diabetes. He administers 50 grams daily. The immediate effect is an expulsion of gas by eruption, and after the first or second day fetid diarrhea with abundant gas. Then tolerance is established and the treatment may be continued. Three cases under his observation showed unmistakable improvement, gaining weight and becoming free of some of the symptoms.

Chittick[3] has used **codein and iodol** with very excellent results in diabetes. He believes that the codein is more efficient, but that the other drug may replace it almost completely. He reports 4 cases, in 3 of which a perfect cure,

[1] Bull. de l'Acad. de Méd., No. 23, 1895. [2] Semaine méd., Aug. 21, 1895.
[3] Physician and Surgeon, Oct., 1895.

apparently, took place. In the fourth there was much improvement. The treatment should invariably be associated with an antidiabetic diet.

West[1] recommends **uranium nitrate** in the treatment of diabetes mellitus. Leconte stated in 1851 that the prolonged use of this remedy will cause glycosuria, and a homeopathic physician first used it in the treatment of the disease, claiming excellent results. West used it in the routine treatment of a number of cases, and met with a great deal of encouragement. He "found, after the drug had been administered a short time only, that all of the patients without exception stated that their thirst was greatly relieved, and the frequency of micturition and the quantity of urine passed greatly reduced." The quantity of sugar usually decreased, and in one case glycosuria ceased entirely. Three cases are reported with some detail, but others gave just as satisfactory results. Regarding the manner of action, he assumes, from the failure of Mr. Symonds to find any uranium in the urine, that the drug is not absorbed and acts within the digestive tract, probably in the way of preventing the rapid digestion of starches and of some of the forms of albumin. He suggests that it may be specially useful in preventing excessive pancreatic digestion. The nitrate is the most useful salt, and should be given, freely diluted with water, after food. A beginning dose of 1 or 2 gr. may be administered twice daily at first; subsequently the dose may be increased. Morrison[2] reports 3 cases of diabetes treated with the same remedy. All were improved, but none permanently.

Gans[3] has determined experimentally that solutions of **common salt** retard the conversion of glycogen into sugar, and suggests that the same action may possibly occur when salt is administered in diabetes.

Ringer[4] precipitates a curd from milk with acetic acid, separates it from the clear fluid, and then rubs it up with calcium carbonate and water until it is completely dissolved. This may be used in place of milk by diabetic patients.

Jones[5] considers that the most hopeful treatment of diabetes is likely to be found in **pancreatic medication,** particularly since true diabetes mellitus is due, in a large percentage of the cases, to degenerative or destructive lesions of the pancreas. As administration by the stomach has been uniformly unsuccessful, he suggests 1 of the 3 following methods as being possibly successful: Rectal injection, subcutaneous injection, or pancreatic grafting. [Notwithstanding the author's hopefulness, it is doubtful if pancreatic medication, however carried out, will prove as useful as he thinks. The percentage of cases in which pancreatic lesions or functional disturbances play a part is still uncertain.]

OSTEOMALACIA.

Allison[6] reports a case of osteomalacia, coming on about the age of puberty, and at the time of observation 43 years old. The patient suffered from extreme deformity of the whole skeleton and severe pains in the affected bones.

The treatment consisted in the administration of a glycerol extract of

[1] Brit. Med. Jour., Aug. 24, 1895.
[2] Ibid.
[3] Centralbl. f. innere Med., Apr. 25, 1896.
[4] Brit. Med. Jour., No. 1823, 1895.
[5] Med. Rec., May 23, 1896.
[6] Edinb. Med. Jour., May, 1896.

healthy marrow, about 4 ounces being given weekly. Improvement was felt on taking the second dose; the pains began gradually to pass away and the patient brightened considerably. Deformity also commenced markedly and progressively to disappear, the most striking improvement being shown in the limbs. A peculiar feature was the spontaneous reduction of existing dislocations. The muscles also developed rapidly, but this was possibly due to massage, which was being carried on at the time, and the patient gained so much power that she was able to support herself. At the end he reports continued improvement in the present case, and some benefit in a case of general bone-weakness and deficiency, due to premature birth; in a case of angular curvature of the spine, due to rickets; and in a case of old-standing, non-suppurative, curvature of the spine.

OBESITY.

Treatment.—Schlesinger[1] reports a case of obesity with improvement from the use of **thyroid tablets.** When the thyroid of the ox was substituted for that of the sheep the patient began to grow fat. This he explains by the fact that the ox thyroid does not contain thyroidin.

Bourneville[2] has investigated the effect of thyroid gland on growth and obesity. In 3 myxedematous idiots the striking points were loss of weight and increase of growth, indicated by enlargement of the waist-measure. It was then tried in 3 cases of obesity in idiots, and their growth was found proportionately more in 4, 5, or 6 months than the average growth of 18 untreated imbeciles and epileptics. The growth was still more striking when compared with the lack of growth before the treatment. As regards obesity, he found that 2 of the idiots lost weight rapidly during treatment, and the third gained during the treatment, but lost rapidly afterward. Generally, the rule was rapid loss during treatment, then a stationary period when the remedy had lost its effect, and an increase after the treatment had ceased.

Eulenburg[3] objects to the unrestricted sale of thyroid preparations, and reports a case in which an obese person produced very severe nervous and cardiac symptoms in himself by taking 6 tablets a day.

Fränkel[4] prepares **thyreoantitoxin** by precipitating an aqueous extract of the gland with neutral sugar of lead, evaporating, dissolving, and precipitating with ether or acetone. He gives an empirical formula of $C_6H_{11}N_3O_5$. This substance produced loss of weight in 3 corpulent men and in a fat dog. It did not produce a fall of blood pressure, but the pulse was accelerated. Kittens from whom the thyroid had been removed were temporarily restored to health by its injection. Fränkel states that it is a pure chemical body of well-defined chemical properties, and that it will prove to contain all the therapeutic properties of the thyroid gland. The preparation is made by extracting the glands with cold water and precipitating with acetic acid.

[4] Wien. klin Woch., No. 48, 1895.

MYXEDEMA.

[Reports showing the beneficial action of **thyroid preparations** have been multiplied during the year. It suffices to note a few of these.] Hertoghe[1] has noted in the treatment by thyroid extract of 9 cases of myxedema, congenital or acquired, that growth was stimulated and intelligence improved, while the bodily weight first diminished, then increased with the increase of height. He also found in 6 cases of children, whose growth was stunted from various causes, that they began to grow, and sometimes rapidly, after this treatment.

A report of unusual interest is that of Murray.[2] The case was that detailed by the author 4 years ago, and the **first instance recorded in literature.** The present account is designed to show the permanence of the beneficial action of thyroid treatment. The patient gradually lost all symptoms of myxedema until she was wholly free from any indication of it, and remains so still. She has continued to take a dram of thyroid extract during each week.

Parker[3] records a striking instance of the beneficial action of thyroid extract in the treatment of cretinism. At $6\frac{1}{2}$ years of age the patient was stunted, unable to sit or stand, stolid, soporose, and unable to speak to or recognize persons. The appearance was that of typical cretinism. The thyroid tabloids were given in doses of 5 grains every day, and in 6 months the child had the appearance of a healthy girl of 2 years of age; was able to sit up and to stand a little, and continued to improve, so that after a year of the treatment she was beginning to be quite well developed. No unpleasant symptoms were caused at any time, but the dose seemed as large as could be administered.

Administration of Thyroid Glands.—Lanz[4] states that the fresh thyroid glands are less toxic than various preparations of the glands, so that it is likely that many instances of so-called thyroidism are really instances of meat-intoxication. Overdoses of fresh thyroid gland, however, occasion a true thyroidism. This may even appear in the young of animals overfed with thyroin during pregnancy.

Huchard[5] advocates the administration of thyroid gland in its natural condition, rather than injections of the juice or extracts, because of the danger of septic infection, and the assurance that the gland is in a fresh condition. The dose is one lobe, 15 to 20 grains, in bouillon, slightly fried or raw and cut in small morsels.

Baumann[6] has obtained a substance from the thyroid gland of sheep which amounts to from 0.2 to 0.5% of the gland and possesses the therapeutic activities. It is almost as powerful as the corresponding quantity of the fresh gland. The substance is an iodin-compound, appearing as an amorphous powder insoluble in water, soluble in alcohol. It contains a notable percentage of phosphorus. The name thyroidin has been given to this substance.

Magnus-Levy[1] has studied the effect of thyroid treatment upon the process of oxidation. The consumption of oxygen above the output varied from 10 to 25%. This indicates the consumption of fat amounting to 50 g. per day for an individual of 90 kg.—a comparatively small amount. The author further refers to the fact that there is a marked loss in Grave's disease, and attributes this to hyperthyroidism, while the diminished loss in myxedema is termed hypothyroidism. V. Noorden found an increase of oxidation amounting to 21%, and sometimes lasting as long as two weeks after the discontinuance of thyroid treatment. A similar increase of oxidation occurred in 1 case of Grave's disease under his treatment.

DISEASES OF THE BLOOD.

Methods of Examination.—Mayer[2] has investigated the sources of **error** in the estimation of hemoglobin **with Fleischl's instrument.** He finds that there are two sources: first, errors of estimation due to imperfect development of the color-sense, to a condition of fatigue, to personal equation, or to the degree of skill on the part of the investigator; second, errors due to imperfections of the instrument itself, difference in size of capillary tubes being the most common among these. Of the errors in technique, imperfect filling of the capillary tubes may cause an error, even when done by a skilled investigator, of more than 14%; in the filling of the cell, different colors are produced when the meniscus is concave or convex, and may cause an error of 5%; the position of the apparatus in relation to the light may cause a maximum error of 6.02%. The scale may be inaccurate and the prism not uniform, and he recommends that a careful scale be constructed for each instrument, testing it with accurately diluted solutions of hemoglobin. Consecutive readings differ in the average by about 2.2%; the maximum difference may be as much as plus or minus 13%. Mayer concludes that in order to get an accurate result by means of a number of examinations it is necessary for the eye to rest for a period between the readings.

Bremer[3] has contributed another article on his method of **diagnosticating diabetes by staining the blood.** His method consists of the preparation of a film of blood on a cover-glass; the fixation of this in a mixture of absolute alcohol and ether, made to boil by immersion of the glass containing it in warm water; and finally, the staining of the blood with eosin and methylen blue. The staining fluid is made by mixing equal parts of saturated aqueous solutions of eosin and methylen blue, collecting the resulting precipitate upon a filter; drying it and dissolving it after addition of small quantities of powdered eosin and methylen blue, in 33% alcohol. In specimens stained in this way he describes the red corpuscles of diabetes as assuming a bright green color, while those of nondiabetic blood are purple or madder-color. He claims to have discovered this reaction in about 50 cases of diabetes and glycosuria, and to have failed in the case of all other affections.

[1] Centralbl. f. innere Med., Apr. 25, 1896.

[2] Deutsch. Arch. f. klin. Med., Bd. 56, Heft. 1–2. [3] N. Y. Med. Jour., Mar. 7, 1896.

The reaction occurred in all forms of glycosuria, excepting in a case of the experimental form caused by phloridzin in rats and in a case of diabetes, with 6.5% of sugar in the urine, in a young boy. Both of these cases should, he claims, be looked upon as essential kidney-diabetes, while the other cases are hematogenous. He suggests that there is some substance in the red corpuscles which gives the peculiar staining-reaction. It is not sugar, and is probably in combination with hemoglobin. [The positive assertions of the author would lead us to believe the method suggested one of great importance. Unfortunately, we have found the test of little value. In our own experience the same green coloration of the erythrocytes occurred in cases in which no glycosuria existed, and was not present in cases in which this condition was present.]

Polycythemia Rubra.—Grawitz[1] has studied the effect of circulatory disturbances upon the blood. He found that with the occurrence of the disturbance of compensation the water of the entire blood and of the serum increases, especially that of the latter. This he explains by the diminished blood-pressure and the absorption of water from the tissues. By tying an artery of a dog the blood of the area of supply was found to diminish in specific gravity by .003, while the dry residue and serum diminished 1.3% and 0.3% respectively. The increased thickness of the blood in chronic disturbances of the circulation he believes is due to loss of water through the lungs; at all events, he holds that there is no increased formation of corpuscles. The blood of the finger-ends he found to be constantly somewhat more concentrated than that of the veins.

Hayem[2] records a case of congenital heart-disease with marked cyanosis, in which the blood-examination showed 7,523,000 red corpuscles and 9920 white corpuscles, while the hemoglobin value of the red corpuscles was 76%. Hayem inclines to the view that the number of the corpuscles in such cases is elevated for the purpose of supplying a greater amount of oxygen-carrying material, and refers to the increased number of corpuscles occurring at high altitudes as being analogous.

Grawitz[3] opposes the theory that the increased number of corpuscles found in the blood of persons residing at considerable elevations is due to the increased formation of corpuscles dependent upon the greater need of oxygen-carrying matter. The increase in number of corpuscles is so rapid that the occurrence of nucleated forms must surely occur, if the explanation given were trustworthy and if our views regarding the occurrence of nucleated corpuscles in conditions of rapid hemogenesis are well founded. Furthermore, the occurrence of such increased formation of blood without notable symptoms of other kinds seems to him doubtful. Finally, he calls attention to the fact that the amount of hemoglobin does not increase with the increased number of corpuscles, and that, indeed, it often decreases; further, there is no evidence of an increase of plasma leading to a plethoric state. Finally, when the patients return to a lower elevation it is notable that symptoms are wanting, and in

[1] Deutsch. Arch. f. klin. Med., 1895. [2] Méd. moderne, No. 50, 1895.
[3] Berl. klin. Woch., No. 33, 1895.

particular that jaundice or other evidence of destruction of the supposed excessive number of corpuscles does not occur. His own explanation, based upon theoretic and experimental evidence, is, that at higher altitudes, in consequence of dryness of the air and the increased respiratory movements, there is a rapid loss of water from the body, and the blood in consequence suffers inspissation with apparent increase of the number of red corpuscles.

The Leukocytes.—Linsey [1] states that he finds, in studying the blood of persons broken down in health, that the white cells contain a greater or less number of vacuoles, and the living matter presents a dull, lustreless appearance, very little refractive.

Gumprecht [2] believes that it is possible to determine histologically the leukocytic degenerations and destruction which lead to the formation of uric acid and alloxins. The characteristic feature of the leukocytes undergoing destruction is disarrangement of the chromatin of the nucleus and indistinctness of the latter. This may be well marked in leukemia, especially in acute cases. In the latter it may affect 10% of the lymphocytes. In chronic leukemia it is seen in the so-called markzellen.

Kuchnau [3] has investigated the **relation of leukocytosis to uric-acid excretion.** He holds that the leukocytes are principally, if not exclusively, the source of the formative materials of uric acid. Increase of uric acid occurs when leukocytosis develops, and is quite independent of fever, since cases running a pyrexial course—as, for example, cachexial leukocytosis—showed increase of uric acid like the febrile cases. Rapid subsidence of leukocytosis is attended with increased excretion of urates. Injection of nuclein and the administration of aseptic pus, suspension of the thymus glands, and the like also cause increase of uric-acid excretion.

Stienon [4] has studied the question of **leukocytosis in pneumonia.** Regarding the morphology, he finds that the polynuclear forms predominate during the febrile stages, the eosinophiles being scarce. After the crisis the small mononuclear elements increase gradually, but in cases of slow resolution the polynuclear remain abundant. The eosinophiles increase as soon as the polynuclear begin to diminish, this occurring early in mild cases, and very slightly or not at all in cases in which suppuration occurs. In some cases the mononuclear forms predominate, this condition persisting during convalescence, and being often accompanied by increase of eosinophiles. The author was unable to observe the stage of preliminary hypoleukocytosis.

Jakob [5] records a series of 15 experiments to determine the manner in which increase and decrease of the number of **leukocytes** occurs **after injection of albumoses.** Unlike Löwitt and Richter, he did not find in any cases alteration in the alkalinity of the blood. The diminution of leukocytes may be asserted to be due to their temporary arrest in the internal organs rather than to destruction.

Pichler[1] has experimented with pilocarpin, nuclein, and antipyrin to determine their influence upon the **number of leukocytes in pneumonia and typhoid fever.** He found increase of the leukocytes following the injection of pilocarpin and nuclein in a number, but not all, cases of pneumonia in which the number of leukocytes had been small. In some cases the number of leukocytes, on the contrary, decreases; similar results were obtained in typhoid fever.

Stein and Erbmann[2] have published most interesting studies of **the leukocytes in tuberculosis.** In beginning phthisis the number of leukocytes is normal; in advanced cases without cavities the number is also normal; but after hemoptysis or cavitic formation leukocytosis is observed; also in cases in which there are other suppurative or carious processes or exudation and hyperplasia of the lymphatic glands. Leukocytosis is therefore of diagnostic importance as indicating cavities when the other causes are absent. They hold that the increase of white corpuscles is due to secondary infections, and not to the tuberculous poison itself.

Wharthin[3] carefully studied **the leukocytes in** 2 cases of **acute miliary tuberculosis.** He found that a hypoleukocytosis was constantly present in both cases. Relatively, there was a marked increase in the polynuclear and transitional forms, and a decrease in the large mononuclears. Eosinophile cells were never found.

Hemolysis.—Biondi[4] has conducted some investigations and observations regarding the seat and nature of hemolysis. He concludes that this occurs after injection of hemolytic substances only in the liver, and that pigment occurring in the spleen is due to the transportation of cells containing degenerating corpuscles or hemosiderin from the liver through the circulation. He was able to demonstrate such cells in the blood of the subclavian vein at the mouth of the thoracic duct, and in the lymph in the thoracic duct itself.

Wenzel[5] records a case of **poisoning by lactophenin** coming on after two weeks' administration of the drug, 1 gr. being taken daily. Suddenly intense jaundice appeared, the stools became light colored, the urine was dark and contained bile. The symptoms slowly subsided. The author attributes the symptoms to destruction of the red corpuscles by paramidophenol. Similar cases have been recorded by others, but in these the dose had been larger.

SYMPTOMATIC ANEMIA.

Reinert[6] has determined **the hemoglobin in** a variety of **neurotic disorders,** and finds that in cases of functional nervous disease, such as hysteria, neurasthenia, it is generally reduced. In one case it was between 30 and 40%.

Capps[7] has made a study of **the blood in general paralysis, and**

[1] Zeit. f. Heilk., Bd. xvii., p. 43. [2] Deutsch. Arch. f. klin. Med., Bd. 56, p. 323.
[3] Med. News, Jan. 25, 1896. [4] Beiträge z. Path. Anat. u. Allg. Path., vol. xviii. H. 1.
[5] Centralbl. f. innere Med., No. 6, 1896. [6] Münch. med. Woch., 1895, No. 14.
[7] Am. Jour. Med. Sci., June, 1896.

also the changes noted before and after **convulsions and apoplectiform attacks.** The study of the blood in the course of the disease shows a slight fall in specific gravity and moderate increase in the number of red corpuscles. The average number of leukocytes was 22% above the normal. The differential count showed a decrease in lymphocytes with a commensurate increase in the large mononuclear cells. In a few cases the eosinophiles were notably increased. The study of the blood in relation with the seizures showed increased red corpuscles and hemoglobin at the time of the convulsions, and decrease after an attack of long duration. Leukocytosis is brought about by the seizures, appearing within a short time of the convulsion or probably not until the convulsion has begun. The intensity and the duration of the leukocytosis vary with the length and severity of the attack. The large mononuclear cells are relatively more increased than other varieties. The author believes the latter fact, and also the fact that mononuclear cells with dark staining nuclei and neutrophilic granules are found, indicate that the theory of leukocytosis being merely a change of distribution of leukocytes is fallacious. [We cannot entirely agree with the author in this, as it is not unlikely that the different forms of leukocytes would be differently affected by influences which are supposed to restrain the leukocytes in the capillaries on the one hand or cause their discharge into the general circulation on the other hand. So far as the peculiar transitonal leukocytes are concerned, we feel the facts are too few to warrant any theories.]

Rochester[1] suggests that **the systolic murmur heard at the aortic valve in anemia** is due to the fact that the blood, being of insufficient weight, has not momentum enough to force the valves flat against the walls of the aorta, and as a result they hang out into the lumen of the vessel and produce an obstruction. The same explanation applies to the pulmonic valve. Regurgitation might be caused by dilatation of the ventricle due to fatty degeneration.

Treatment of Symptomatic Anemia.—Quincke and Hochhaus, at the Congress of Internal Medicine,[2] reported their investigations of the **absorption and elimination of iron.** These experiments were carried out upon mice, and the studies were made by microchemical methods. It was found that the iron of the food or that administered is absorbed exclusively from the duodenum. The elimination of iron takes place from the large intestine and cecum, and by the aid of the leukocytes and epithelium rather than through the glands. Kunkel[3] publishes experiments upon two dogs which indicate that the administration of iron increases the amounts of iron in the various tissues of the body as well as in the blood. The first dog was fed on milk, with the addition of a liquid preparation of albuminate of iron; the second with milk without such addition. The animals were bled from time to time, and the amount of iron abstracted was estimated. After 8 weeks both

[1] Med. News, Dec. 7, 1895.

[2] Centralbl. f. innere Med., Apr. 25, 1896; Berl. klin. Woch., Apr. 20–27, 1896.

[3] Pflüger's Archiv, Bd. lxi. p. 595.

animals were killed, and the amount of iron was found to be 1½ times as great in the blood of the dog which received the iron as in the other, while the amount in the liver was 8 times as great. In all organs there was an excess.

DaCosta [1] after considerable experiment finally discovered a compound of **iron** which was stable and nonirritating, and therefore suitable **for hypodermic employment.** This is the "ferrous manganese citrate." He reports 3 cases of secondary anemia treated by this method with great improvement. He considers that he is the first one to have published cases in which iron was used hypodermically. In conclusion he states that the dose for hypodermic use should not, in the beginning, be more than one-half of that given by the mouth. He himself has never seen any disagreeable complications from its use.

De Francesco [2] reports 3 cases of severe anemia in which injections of **mercuric chlorid** and **quinin** were used with good results. The cases were not specific in nature. [We have ourselves obtained striking results from protracted administration of small doses of mercuric chlorid.]

Touatre [3] declares that inhalations of chemically **pure oxygen** is the most efficacious remedy in diseases of the blood, increasing the number and the energy of the red corpuscles, multiplying the leukocytes, and facilitating the elimination of the toxins. Among other diseases, it is useful in nephritis, particularly the acute forms.

Caroline Pease [4] reports 7 cases of simple anemia treated with **bone-marrow.** The preparation used was made by macerating finely broken sheep's ribs containing red marrow in glycerol for 4 days at a temperature of 70° F. and straining the resulting liquid. As much as a dessertspoonful could be given 3 times daily, but more than this proved laxative. Under this treatment in the course of 5 weeks the hemoglobin was increased from an average of 47% to an average of 87%, and the number of red corpuscles from an average of 4,084,000 to an average of 4,731,000. The leukocytes decreased from 15,000 to 6000.

Watkins [5] reports a case of anemia in which **carnogen** in doses of 2 drams 3 times a day was given, and all other treatment suspended. The patient rapidly improved and the blood became normal. Taube [6] used somatose in doses of 10 g. per day with excellent results in post-typhoid anemia and in chlorosis. Richardson [7] found ferratin useful in 5 cases; while Reimer and Frisch [8] advocate corniferrin, though gastric disturbances occurred in 2 cases.

Venesection.—Koeppe [9] has studied the effect of venesection experimentally. He particularly calls attention to the fact that nucleated red corpuscles occur at the time when the red corpuscles reach their lowest number,

[1] Therap. Gaz., May 15, 1896.

[9] Münch. med. Woch., No. 39, 1895.

and further refers to the large numbers of microcytes, believing these to be formed by segmentation of the red corpuscles so as to form a greater surface for purposes of oxygenation. Ziegelroth[1] found that the specific gravity of the blood decreases greatly in the blood of the lobe of the ear after venesection, but increases above the normal in 6 hours, and reaches the normal again in 12 hours.

CHLOROSIS.

Charrin[2] regards chlorosis as a menstrual autointoxication, due to insufficient development of the genital organs in consequence of hereditary influence and the retention of toxic elements normally excreted with the menstrual discharge. [This return to the theory of Hippocrates is interesting as an instance of reversion of opinion to ancient belief.] Hunter[3] in a discussion on pernicious anemia points out that the supposed intestinal origin of chlorosis, according to the views of Sir Andrew Clark, is founded rather upon a clinical than an experimental basis. He himself holds to the hemogenic origin of chlorosis. He does not deny that it is a form of intestinal anemia, but maintains lack of proof. Stockman[4] holds that excessive menstrual loss or less frequently other forms of hemorrhage are important. The insufficient ingestion of iron with the food, resulting from want of appetite, and possibly an inherent want of blood-making power in certain persons, are also important. Henry[5] in discussing chlorosis classifies it as one of the primary anemias. He recognizes 3 types—that in which the corpuscles are of normal size and number with deficiency of coloring matter; that in which they are diminished in number with deficiency of coloring matter; and that in which they are diminished in size, but of normal number and normal percentage of coloring matter. He believes that iron is the most efficient therapeutic agent. [The importance assigned by the author to reduction in the amount of hemoglobin is such as our experience would lead us to assume. The opinions of those who hold that the relative decrease in the amount of coloring matter is a "phenomenon of regeneration"—that is, a secondary result growing out of the more rapid regeneration of corpuscles than hemoglobin—certainly want confirmation.] Townsend[6] records a series of cases of chlorosis with the particular intention of illustrating the value of treatment. In the first series there were 87 cases in which the percentage of hemoglobin varied from 18 to 72, the average being 35.5. The youngest patient was 15 and the oldest 34. The most constant symptoms were the cardiac and the arterial. Headache was present in 74%, dyspepsia in 75%, constipation in 65%, irregular and scanty menstruation in 54%, and profuse menstruation in 11%. In 2 cases the menses had never occurred. Regarding the general appearances, it was found that the condition of the nails was the best indication, pallor having occurred in this situation in 95% of the cases. The condition of the conjunctiva was notably

[1] Virch. Archiv, cxli. 2, 1895.
[2] Gaz. Hebdom. de Méd. et Chir., Jan. 2, 1896.
[3] Brit. Med. Jour., Feb. 8, 1896.
[4] Ibid., Dec. 14, 1895.
[5] Univ. Med. Mag., Aug., 1895.
[6] Boston M. and S. Jour., May 28, 1896.

unreliable, the color being pale in 64%, fair in 25.5%, and quite good in 10.5%. The statistics regarding the arterial murmurs agree with those of other writers. Stockman[1] gives the statistics of 63 cases of chlorosis, in all of which there was a great deficiency of hemoglobin, and generally also of the red corpuscles. In 3 of the cases poikilocytosis was extreme, in 10 marked, and in only a few no alteration whatever; 12 of the cases suffered from amenorrhea and 39 from disturbances of menstruation; in only 4 was menstruation normal; 11 of the cases were suffering from a second attack, and 22 had had frequent attacks, some being properly described as cases of chronic chlorosis.

Treatment of Chlorosis.—Fütterer[2] suggests a novel method of treatment for cases of chlorosis with hypoplasia of the heart and aorta. The enlargement of the vascular channels found postmortem in case of beer-drinkers suggests to him that increasing the quantity of liquids may serve to dilate the heart and vessels, and thus beneficially influence chlorosis, and possibly prevent the development of other diseases dependent upon hypoplasia of these structures, notably tuberculosis. He orders the patients to continue their usual mode of living for two days, and to measure all the liquids they take. The average quantity being found, he orders a quart more of milk to be taken each day until the highest possible limit has been reached. Different patients range between 3 and 9 quarts daily, while most of them will take from 5 to 6 quarts, this being in addition to the quantity they used before the treatment began. They may take pure or boiled milk, or, if this occasions inconvenience, milk and water. The patients increase rapidly in weight, the increase in his cases varying between 3 and 35 pounds within 4 months. The iron-treatment then proves entirely satisfactory, though before it had been unsuccessful. [Undoubtedly forced feeding is useful in the treatment of chlorosis, though the beneficial effect may not result as the author believes.]

Townsend[3] has investigated the value of **intestinal antisepsis** in the treatment of chlorosis. In 30 cases beta-naphtol was given, cascara being used for constipation; in 31 cases Blaud's pill (5 gr. 3 times daily), cascara being used in these cases also. In the first series the improvement per week in hemoglobin averaged 1.85%, in the second group 5.07%. Cathartics alone were used in 7 cases, and the improvement amounted to 1.50%. Blaud's pill after a preliminary treatment with beta-naphtol was employed in 12 cases, and the improvement amounted to 6.7%. Blaud's treatment without the preliminary treatment was used in 19 cases, and the improvement was 4.5% per week. Later a series of cases were treated with a combination of beta-naphtol and Blaud's pill, and the average improvement was 7.9%. It will be noted that the last was the most favorable result of all. Stockman[4] in discussing the treatment of chlorosis holds that clinical experience has shown **iron** to be the most important remedy, but the administration should be continued as long as 8 or 10 weeks. The choice of a preparation must be guided

[1] Edinb. Med. Jour., Nov., 1895.
[2] Jour. Am. Med. Assoc., Nov. 30, 1895.
[3] Loc. cit.
[4] Loc. cit.

by the condition of the stomach. No one preparation can be said to be better than another. Large doses are probably more efficacious than small. Manganese or arsenic is either useless or unnecessary. Finally, he refers to the importance of diet, rest in bed, and proper surroundings.

PERNICIOUS ANEMIA.

Pepper[1] reports a case of pernicious anemia due to ileocolitis. The patient presented the characteristic features of Addisonian pernicious anemia, the general appearance as well as the condition of the blood being pronounced. There were considerable mucous colitis and gastric disturbances. Lavage of the intestines was practised with striking results, the patient leaving the hospital in a few weeks much improved. [Subsequently the patient reports progressive increase in weight and strength. The interesting case of Juergens, in which similar improvement occurred after free purgation and discharge of immense numbers of bacteria termo, is analogous; and both cases speak in favor of the view that pernicious anemia may be of gastrointestinal origin.]

Bowen[2] reports that in a case of intense anemia in Barbados he found numbers of **ankylostoma** in the intestinal tract postmortem. Investigating the injections from another case of anemia, coming from an entirely different part of the island, he found eggs of the characteristic appearance. Administration of anthelmintics and purges brought away numbers of the parasites. This seems to be the first contribution indicating the occurrence of ankylostomiasis on the island of Barbados. [European writers have stated that ankylostomiasis occasionally occurs in certain parts of the United States, but there seems to be little evidence in favor of this view. In our own somewhat hasty examination of the literature we find no recorded cases in native Americans, and only 1 instance in an immigrant.]

Herrick[3] reports a case of extreme anemia, showing all the characteristics of pernicious anemia, **following a fall** upon the sidewalk in which the patient hurt his back and left side. The red corpuscles were reduced to 600,000, and there was a slight relative increase in the leukocytes, particularly the lymphocytes. The hemoglobin was 25%. The patient improved markedly under arsenic and passed from observation. In the discussion that followed Musser reported 2 cases following, if not due to, nervous influences. Anxiety and grief in these cases were followed by severe digestive disturbances, and these by the alterations in the blood.

Stockman[4] has published **analyses of the liver and spleen** showing the amount of iron per 100 g., and in the whole organ in various diseases. From these analyses it appears that the view that has been held by some that pernicious anemia is the only disease in which increase of iron occurs in these organs is unfounded. In defence of his previously published view, that the iron deposits of pernicious anemia are dependent upon the absorption of internal hemorrhages, he cites the fact that the cases studied by him were cases in

[1] Med. News, Nov. 23, 1895.
[2] Internat. Med. Mag., Apr., 1896.
[3] Jour. Am. Med. Assoc., June 20, 1896.
[4] Brit. Med. Jour., May 2, 1896.

which interstitial bleedings had taken place, while in those cases of fatal anemia where the blood-loss was external there was very little iron in the organs. Further, after artificially-made subcutaneous hemorrhages in rabbits and during absorption of large external hemorrhages in man (hematocele, scurvy), iron is plentifully deposited in the liver and a large amount of yellow pigment is formed from the hemoglobin.

Hunt [1] reports 3 cases of pernicious anemia which were treated with extract of **bone-marrow.** The first case improved so rapidly under arsenic by the mouth that no other treatment was tried until a return of the condition occurred 5 months after discharge from the hospital. No improvement occurred, and the patient died. The second patient, also improved under arsenic, was discharged and remained well for 18 months. Red bone-marrow was used at first during the relapse, and, no improvement being apparent, arsenic was again tried, but unavailingly. Yellow marrow was then tried, but the patient died 4 days after it had been commenced. The third patient was kept for a week without treatment, and then given red bone-marrow for 3 weeks. No improvement taking place, she was given arsenic, and the blood and general health rapidly returned to normal. He concludes that the red marrow did not have the slightest effect in any of the 3 cases. Hunt sees no rational explanation for the use of bone-marrow in anemia, for digested bone-marrow can hardly aid in the formation of new corpuscles, and as the existing bone-marrow is hypertrophied, there is no reason to suppose that the organism lacks any substance that it may secrete.

Danforth [2] reports an interesting case of pernicious anemia in which, after trial of the various forms of iron, intestinal sepsis, and arsenic without benefit, bone-marrow was administered—at first the yellow marrow, raw, by the mouth, and later a glycerol extract of red marrow. Improvement took place, which continued for some months, and was then followed by relapse, until, at the end of 18 months after the institution of the marrow treatment, it apparently lost its effect and the patient died. Danforth believes that life was prolonged for at least 18 months. A case of pseudoleukemia was treated in the same manner with most extraordinary improvement, followed in 2 months by a fatal relapse. He has also used it in a number of cases of simple anemia with beneficial results, finding a glycerol extract of red marrow to be most efficient. In the discussion that followed Smith of New York reported a case that presented a period of extraordinary improvement without any treatment whatever; Henry of Philadelphia, a case that had been cured for 2 years by the use of enormous doses of arsenic; Hare of Philadelphia, a case that showed 2 periods of marked improvement, 1 under arsenic and 1 under no treatment.

Stengel [3] believes that pernicious anemia is **a hemolytic disease** in which the hemogenesis may or may not be equal to the normal, although always insufficient to cope with the hemolysis, and that the hemolysis originates in the gastrointestinal capillaries as a result of the absorption of toxic

[1] Lancet, Feb. 1, 1896.

[2] Chicago Clin. Rev., June, 1896.

[3] Ther. Gaz., May 15, 1896.

substances. He considers all cases in which a maximum degree of oligocythemia with microcytosis, macrocytosis, and poikilocytosis occurred, and in which nucleated red corpuscles were discovered, and the hemoglobin was relatively excessive or at least approximately equal in percentage to that of the corpuscles, as pernicious anemia. He divides the treatment under three heads: specific, that directed to the general conditions of the circulation, and treatment of the intestinal conditions and underlying affections. The specific treatment consists in the use of iron, arsenic, and bone-marrow. Iron he considers of little value, but arsenic, he thinks, acts in some way to prevent blood destruction, and perhaps also as a stimulant to hemogenesis. He reports 2 cases in which marked improvement was obtained by the persistent use of this drug. Bone-marrow apparently acts differently according to the preparation that is employed. He reports 2 cases in which this treatment was employed; in the first a glycerol extract of marrow and large doses of arsenic had had no effect, but "red bone-marrow jam" produced immediate and extraordinary improvement. In a subsequent relapse it was of no value. In the second case the patient was far advanced in the disease, and no effect was produced. Of the treatment designed to improve the conditions of the circulation, perhaps the most valuable are colonic douches employed to relieve the quantitative anemia. Intestinal antiseptics usually fail to control fermentative processes, and their use in pernicious anemia is therefore doubtful. [A careful study of the reported cases in which bone-marrow has been used leads to the conclusion that no dogmatic statement is warranted. Our own experiences in some 4 or 5 cases have been conflicting.]

Patera[1] reports a case of severe anemia (pernicious anemia) in which the usual plans of treatment were adopted without striking effect. Later, **mercuric chlorid injections** were used, 5 mg. being administered daily for 2 months. Under this treatment the anemia disappeared and the patient improved in every way. The author also refers to 2 other cases in which this treatment was employed with excellent results.

Ewald[2] reports a case of extreme anemia having the features of pernicious anemia in which, as a last resort, **transfusion** was practised. The blood was taken from the patient's wife, defibrinated, and injected into the vein, the amount being about 85 cc. There was slight improvement immediately, but stimulants were required during the following night. On the second day the strength gradually returned, and by the third day the blood showed 1,250,000 red corpuscles and 29% hemoglobin; after 2 weeks there were 2,300,000 red corpuscles and 33% hemoglobin; while 5 months later the hemoglobin was the same, though the red corpuscles had increased to 3,500,000. The author discusses the pathology of the disease, and inclines to regard it as a form of intoxication, believing, moreover, that transfusion of blood may exercise an antitoxic or neutralizing effect which gives the body time to regain strength. The patient reported received arsenic in various forms with tonics and intestinal antiseptics throughout the case. [The case is instructive in showing

[1] Riforma Med., May 28, 1896.

[2] Berl. klin. Woch., No. 45, 1895.

the effect of injection of liquid at a time when the circulation is at its lowest point. It is inconclusive as illustrating any special effect derivable from blood transfusion, and the assumption that the blood exercises antitoxic power is purely theoretical. The increase of the number of corpuscles without increase of hemoglobin is characteristic of the disease, as it is also a usual condition in other anemic affections during the stage of regeneration of the blood.]

LEUKEMIA.

Mannaberg [1] reports a case of lymphatic leukemia in which the lymphocytes were found to contain sharply circumscribed colorless bodies which showed ameboid movements even when cold. Staining showed that these were not products of cellular degeneration. The author believes them to be **protozoa,** and refers to cases of leukemia in literature which recovered under the use of quinin (Mosler, Ehrlich). His own patient lost 5 kg. in 3 weeks while taking this remedy, and the author attributes this to reduction in the tumors.

Hindenburg [2] believes that leukemia is due to a **mitotic increase of a certain kind of leukocyte** in a pathologic manner as a result of the action of some cause as yet unknown. He thinks that the idea that the leukemic condition of the blood is due to decreased leukolysis cannot be true, because he finds numerous degenerated forms in the organs.

Robison [3] reports a case of **splenic leukemia,** in which, 6 years before admission, a small painful tumor was noticed in the region of the spleen. There had been repeated injuries to this region of the abdomen. The blood contained 1,820,000 red blood-cells per c.mm., and the proportion of white to red was 20%.

Symptoms.—Kast [4] reports a case of leukemia in which **priapism** suddenly developed and continued for 2 months, subsiding slowly and permanently. At this time leukemia was recognized by the enlargement of the spleen and condition of the blood. The patient died 6 months later, and the cause of the priapism was found to be excessive white thrombosis of the cavernous bodies; this had been followed by connective-tissue hypertrophy and induration.

Seelig [5] reports **a case of acute leukemia** occurring in a boy of 11 years. The boy had been ill for 2 years with postscarlatinous nephritis, when he began to lose strength and suffered with headache, nausea, and disturbances of his stomach. The spleen was enlarged, but the blood-examination was negative; 16 days later he had edema of the eyelids, enlargement of the lymph-glands, and swollen and bleeding gums. The blood showed great increase of leukocytes (1 to 5.4); there were pain and tenderness of the tibiæ and subcutaneous nodules and hemorrhages in the skin. Death occurred 4 days later, and the autopsy revealed the characteristic lesions of spleen, liver, lymph glands, bone-marrow, and other organs. Unusually large lymphomata were

[1] Centralbl. f. innere Med., Apr. 25, 1896; Berl. klin. Woch., Apr. 20–27, 1896.
[2] Deutsch. Arch. f. klin. Med., Bd. liv. S. 209.
[3] N. Am. Pract., July, 1895.

[5] Deutsch. Arch. f. klin. Med., Bd. liv. p. 537.

found in the epicardium. Examinations of the blood had shown large numbers of myelocytes, but "granulations in Ehrlich's sense" could not be found. There were but few nucleated red corpuscles. A later examination of the blood and that made after death showed preponderance of lymphocytes.

Whait[1] reports a case of leukemia which seems to illustrate the usefulness of **bone-marrow** as a measure of treatment. At first arsenic was used without notable improvement for 17 days; then bone-marrow was added, and immediately the leukocytes decreased in number, falling from 340,000 to 190,000 in a few days. In the course of the next 2 weeks the number declined to 40,000, and subsequently became almost normal. Neuritis developed and bronzing of the skin was produced, so that arsenic was finally withheld. The patient disappeared from view in February, practically well, the spleen and blood having been normal for several months. In August she returned with the symptoms as marked as ever, the liver and spleen very much enlarged, and the leukocytes numbering 225,000. She was given tabloids of marrow with carbonate of iron, and there was immediate improvement. In 2 weeks the number of leukocytes had fallen to 41,000. (See Fig. 1.) She further

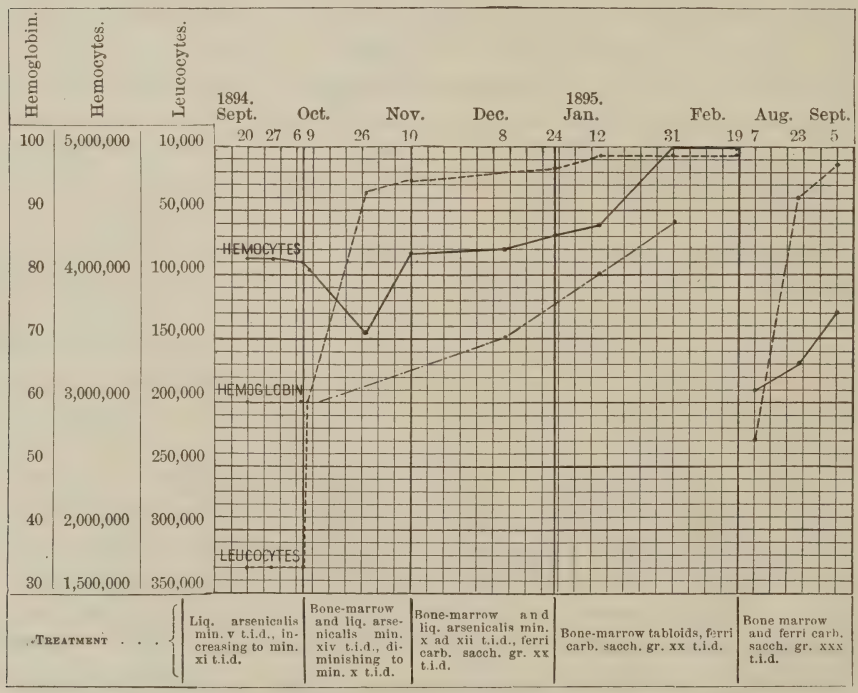

FIG. 1.—Chart showing improvement in the condition of the blood during the administration of bone-marrow (Brit. Med. Jour., April 4, 1896).

progressed favorably till the beginning of September, when pulmonary congestion and pleurisy supervened and the patient died. Nammack[2] reports a case of leukemia treated with fresh bone-marrow. The blood count showed at first

[1] Brit. Med. Jour., Apr. 4, 1896.

[2] Med. Rec., Dec. 14, 1895.

2,680,000 red cells and 864,000 white cells, or a ratio of 3 to 1; hemoglobin, 50%. The ratio gradually changed to 13 to 1, and the spleen diminished in size. A preparation of bone-marrow was used in the latter part of the cure.

Hodgkin's Disease.—Katzenstein[1] reports a case of pseudoleukemia of two months' standing in which there was marked anemia, moderate increase of the white corpuscles, with decided enlargement of the spleen, enlargement of the lymph glands, and troublesome prurigo. Subcutaneous injections of arsenic were employed and continued for 6 months, when the patient had almost wholly recovered, and continued so for 5 months.

Picou and Ramond[2] describe a case, similar to one detailed by Gaucher, as an instance of **primary epithelioma of the spleen.** Their patient was a young woman of 32 who had become gradually ill with enlargement of the spleen and a dull pain in the left side. Coincidently, the liver enlarged and the entire abdomen was swollen by these viscera. There was no ascites, and the hypertrophy of the organs was smooth and regular. Dyspepsia, constipation, dyspnea, frequent urination, edema, and at times cramps of the lower limbs were among the symptoms, while hemorrhages constituted a marked feature of the case. These took the form of epistaxis, subcutaneous hemorrhages, and the like, and the gums became soft and spongy as in scurvy.

Gaucher laid particular stress upon the absence of glandular enlargement and anemia without leukemic characters. The duration of the disease is protracted. The anatomical lesions consist in enlargement of the liver and spleen, both the organs presenting their normal shape. The spleen is paler than normal and the parenchyma sclerotic, the trabeculæ being much increased in thickness. Microscopically, the proper substance of the spleen is found to be destroyed, its place being taken by alveoli formed with thickened trabeculæ filled with sharply defined nuclei. The liver presents evidences of cirrhosis. The authors conclude that the disease resembles endothelioma, but were unable to trace an endothelial origin in their case, and were inclined to regard it as carcinoma. [The nature of these cases is very doubtful, but they may be included in this place as probable instances of lymphadenoma of unusual type beginning in the spleen. There seems little reason to classify them as cases of carcinoma.]

Banti[3] refers to the occurrence of **cirrhosis of the liver after splenic enlargement** in cases of anæmia splenica. He has observed 10 cases in the last 13 years. The anemia may precede the enlargement of the spleen or may follow it, while the cirrhosis of the liver is the last to occur. It presents the character of atrophic cirrhosis, but is an independent infection. He believes the sequence of events is primary irritation of the spleen by some poison, and secondary implication of the liver. Extirpation of the spleen sometimes causes recovery, which illustrates his view that the cause of the anemia occurs in the spleen.

Köster[4] records a case of splenic anemia or pseudoleukemia much improved

[1] Deutsch. Arch. f. klin. Med., Bd. lvi. H. 1–2. [2] Arch. de Méd. exper., Mar., 1896.
[3] Sperimentale, Feb., 1895. [4] Centralbl. f. innere Med., Jan. 26, 1896.

by the administration of **oxygen.** The patient, a man of 44, had influenza 2 years before, and suffered from general weakness, dyspnea, and palpitation. The complexion was yellowish, and red corpuscles numbered 800,000, while hemoglobin was but 25%; there were numerous microcytes as well as poikilocytes. Under arsenic and quinin the patient grew worse; then inhalations of oxygen were given daily as a last resort. A considerable improvement at once set in, and in 2 days the splenic enlargement began to subside and the blood to improve. In a month an examination showed 3,800,000 red corpuscles and 75% hemoglobin, and 2 months later the spleen was normal in size.

ADDISON'S DISEASE.

Etiology.—Boinet[1] has experimented upon rats to determine the nature of Addison's disease. In 109 animals both suprarenal glands were removed; in 20 the glands were ligated; and in a series tincture of iodin, silver nitrate, and other cauterizing agents and pus from inflammatory and tuberculous lesions were injected. It was found that lesions of the glands led to accumulation of pigment in the blood and to pigmentation of the internal organs —in one-half of the cases in large quantity, in one-quarter of the cases in small quantity, and not at all in the remaining quarter. Sometimes there was marked paresis with gradual asthenia. Injection of an extract prepared from the muscles of such rats caused toxic and fatal results in other rats. Hansemann[2] reports a case of Addison's disease with autopsy, in which all the organs were found practically normal excepting the suprarenal bodies. In these there was absence of the cortical substance and some round-cell infiltration. Sibley[3] reports a case of Addison's disease occurring in a girl of 20 years. Upon admission she was nearly mulatto-colored, and there were deep bands of staining in the line corresponding to the pressure of the waistband and above the knees in the position of the garters, and patches of pigment on the mucous membrane. No physical signs of disease could be recognized. The patient died in collapse, and at the autopsy all the organs were found to be healthy with the exception of the suprarenal capsules, which were very hard, cutting like scirrhus and without distinction between cortex and medulla. No physiologically active extract could be obtained from the glands. Microscopically, the glands showed nothing but fibrous and caseous tissue in various stages of degeneration, with considerable small-celled infiltration in places. No tubercle bacilli were found.

Treatment.—[Theoretically, the use of extracts of suprarenal glands commends itself in the treatment of Addison's disease, and favorable reports have been reported. The number of cases, however, is small, and the results have not been wholly satisfactory.] Sydney Ringer and Phear[4] record a case of Addison's disease treated with suprarenal extract, and summarized 9 reported cases, 5 of which showed improvement, though a sufficient time had scarcely elapsed to determine whether the improvement was permanent. In 2

[1] Semaine méd., No. 8, 1896.
[2] Berl. klin. Woch., Apr. 6, 1896.
[3] Lancet, May 23, 1896.
[4] Brit. Med. Jour., Jan. 18, 1896.

cases there was no improvement, in 1 only a limited trial was given, and in 1 death occurred in spite of the treatment. Another case was a woman of 28 years who had presented the symptoms for 2 years; there was great disturbance of the stomach, excessive weakness, some loss of flesh and pigmentation of the face, hands, forearms, axillæ, about the knuckles, over the kneecap, and in the neighborhood of the toes and ankles. The mucous membranes were pigmented in patches. Suprarenal extract was given daily to the amount of 45 gr., and increased to 420 gr.; rapid improvement followed in the general condition as well as in pigmentation. The improvement continued for 4 weeks, when there was a decided change for the worse, and death occurred 6 weeks after the commencement of the treatment. In the discussion of this case Dr. Parkinson related the case of a man of 31 years under the care of Dr. Murrell treated in the same way without beneficial results. Murrell [1] reports a case of Addison's disease that was treated first with tabloids of suprarenal capsule extract, each representing 5 gr. of the extract 3 times daily. Nausea and vomiting were worse, and he lost weight. Four tablets increased the symptoms so much that the treatment was changed to fresh suprarenal capsules, taken at first from the sheep, and then the calf. The condition grew rapidly worse and death occurred.

Osler [2] reports at length 6 interesting cases of Addison's disease, in only 1 of which anemia existed. The most interesting case is the 6th. In this the symptoms were most marked, the pigmentation being extreme, with marked asthenia and emaciation. Tubercle bacilli had been found in the sputa. Upon the 16th of May treatment with suprarenal extract was begun. Fresh suprarenals obtained from pigs were extracted with glycerol, so that 1 dram of the extract equalled 1 dram of fresh suprarenals. Half a dram was given 3 times a day. Immediate improvement took place, and in 8 days he had gained 3 pounds in weight. Later the dose was increased and the improvement continued. By Sept. 10th he had made a total gain of 19 pounds, and was bright and active, and said he felt vigorous. Subsequently his condition remained good, he was enabled to work, and there was probably a slight diminution in the amount of pigmentation and the patches on the palate had completely disappeared. Curiously enough, the tubercular process was also favorably affected.

Francis [3] reports a case of Addison's disease in a young man of 25, and in which suprarenal extract was administered with striking results. The patient was first seen on Sept. 1st, when he was vomiting and presented an emaciated appearance. The skin was dark, especially around the eyes, on the backs of the hands, and in certain other localized portions. There were spots on the mucous membrane. He was put in bed, and tabloids containing 5 gr. of the dried gland were given 3 times daily; 2 days later vomiting ceased, and 2 days after that he was able to take solid food. In the next 9 days, with the same treatment and cod-liver oil and syrup of hypophosphites, he gained

[1] Lancet, Feb. 1, 1896.

[2] Internat. Med. Mag., Feb., 1896.

[3] Brit. Med. Jour., May 2, 1896.

strength so as to be able to walk without assistance. The improvement continued during October, and he gained flesh rapidly—at one time 2½ pounds in 9 days. The pigmentation was growing visibly less, and he went to London to seek work. A relapse occurred and the patient died. Autopsy does not appear to have been performed.

Stockton [1] reports a case of Addison's disease in which all the characteristic symptoms were extremely developed. Hydrochloric acid was not found in the stomach contents, and only a trace of lactic acid. Above the left kidney an irregular-shaped body, about the size of a hen's egg, was felt, supposed to be a diseased adrenal. The patient had been taking iron and arsenic; these were continued, and in addition 5 gallons of oxygen 3 times a day and 2 uncooked adrenals from a sheep were prescribed. Improvement was prompt and continuous, the blood count rising from 1,800,000 red cells and 30% hemoglobin to 4,000,000 red cells and 80% hemoglobin, whilst the bronzing rapidly faded.

Quine [2] reports a case of Addison's disease treated with suprarenal bodies. The medicine apparently disagreed with the patient, but she continued taking it, and on the 9th day a temperature of 100.5° was observed; 2 days later the temperature was 102°; there were nausea and extreme faintness. The treatment was then stopped, and death occurred 4 days later.

Hemophilia.—Wright [3] discusses the treatment of hemorrhages and urticarias associated with deficient coagulability of the blood. He found that in the case of a boy with very severe hemophilia the coagulation period exceeded 54 minutes at a temperature of 18.5° C. After two 2 g. doses of **calcium chlorid** it was diminished to 25 minutes, and after a further dose of 2 g. to 13½ minutes. At a later period the normal duration of coagulation was 14 minutes, but after 20.6 g. doses this was reduced to 6¾ minutes. Similar results were observed in the brother of this patient, who suffered from a less severe type of the disease. He mentions several cases that have come to his notice where hemophilic children prior to an attack of their disease exhibited a great desire to eat plaster and water. For the treatment of the hemorrhage itself he has found nothing so beneficial as the inhalation of carbon dioxid gas. As he has observed that the blood of hemophilic patients and of their femal ascendants is characterized by a notable paucity of white blood corpuscles, and especially by a relative paucity of the polynuclear white blood corpuscles, he advocates the employment of nucleoalbumins locally in order to promote the formation of a sound clot. According to his experience, wine has the effect of notably diminishing the coagulability of the blood, and therefore in cases of urticaria and hemophilic bleeding it is contraindicated.

Scurvy.—Neale,[4] being compelled to winter in the Arctic regions with very short rations, successfully avoided the development of scurvy in his party by the use of frozen fresh blood. Another party that wintered in the neighborhood and refused to take this precaution had scurvy very badly. He considers that scurvy begins with anemia and is largely due to improper hygiene.

DISEASES OF THE LUNGS AND PLEURÆ.

Miscellaneous.—Litten[1] in speaking of the **diaphragm phenomenon,** first described by himself, states that it achieves its greatest triumph in unilateral thoracic conditions. If absent on one side and normal on the other, there is a considerable effusion of liquid or air into the affected pleural cavity, or else pneumonia of the lower lobe. In the case of serous effusion slight diaphragmatic motions are often visible abnormally far downward. An area of dulness in the lower part of the thorax, not due to the liver or spleen, whilst the phenomena is visible above the dulness, but diminished, indicates subphrenic abscess. In a case of acquired diaphragmatic hernia the phenomenon was visible below the area of tympanites. The diaphragm phenomenon is the visible horizontal depression crossing the lower part of the sides of the chest and moving up and down with the respirations. It represents the movement of the diaphragm as the lower edges of the lungs become inflated or collapsed.

Cary[2] has made certain studies to determine the causes of the greater **vocal fremitus and vocal resonance** at the right apex than at the left. Casts made by filling the bronchial system with molten metal showed that the branch of the right bronchus supplying the upper lobe is given off close to the bifurcation, and thus the most direct and shortest column of air entering the lungs is that passing to this portion of the lungs.

Compte[3] describes the **phonendoscope** of Bianchi. This instrument, designed to permit the use of auscultation and percussion, consists of a shallow metal cup covered by a disk of ebonite, with a perforation in the cup to which are attached rubber tubes for the ears. From the center of the disk of ebonite arises a little rod with a button at the end. The button is placed over the organ to be examined and the tubes in the ears, whilst the finger is drawn over the skin, beginning at the point where the button is applied and running outward. As soon as the finger passes beyond the organ over which the button is applied the rasping bruit, heard before, ceases. This change of sound is said to be decidedly marked.

Robinson[4] mentions various **causes of cough** that are usually overlooked. Among these are enlarged lingual tonsils. Hemorrhage may occur in this condition, and is apt to be mistaken for hematemesis. Another cause, common in young children, is the development of the pharyngeal tonsil or lymphoid tissue at the vault of the pharynx. A third cause is one or more hypersensitive areas in the pharynx, the tonsillar region, upon the soft palate, or in the hyoid or epiglottidean fossa. A fourth cause is irritation of the auditory canal. Other causes are—a weak or dilated heart, pleurisy, an enlarged spleen or liver. The treatment suggested is of course local or removal of the cause, antilithic remedies, change of climate, etc. Babcock[5] speaks of the

[1] Med. Rec., Dec. 28, 1895.
[2] Amer. Jour. Med. Sci., Oct., 1895.
[3] Compt. rend. Hebdom. de la Soc. de Biol., Mar. 6, 1896.
[4] Am. Jour. of Med. Sci., Nov., 1895.
[5] Canad. Pract., Apr., 1896.

presence of lingual tonsils as the cause of chronic cough. He reports a case in which chronic cough and symptoms of congestion at the left apex were due to an enormously dilated left auricle in a case of mitral regurgitation.

Marie[1] discusses certain **thoracic deformities** that occur in medical affections. He first describes the funnel-shaped thorax, which has no pathologic significance; then the tailor-chest, shoemaker's chest, and the gutter thorax. All these deformities are very likely to occur in connection with other congenital malformations in the same individual. Frequently patients with a funnel-shaped thorax exhibit certain psychical deformities, and it is to be taken therefore as a sign of degeneration. Often many members of one family may present these deformities, and it must therefore be looked upon as a morbid condition of hereditary nature. The prow-shaped thorax or the boat-shaped thorax is often associated with congenital anomalies of the heart, and apparent deformities occur in the myopathies due to the degeneration and wasting of the muscles of the upper part of the chest. Another deformity that occurs in the myopathies is the wasp-waist, characterized by the almost vertical position of the ribs, and due to the flattening of the thorax, not unlike in its nature that which occurs in the skull of patients suffering from myopathies.

Thayer[2] reports 3 cases of **osteoarthropathy** associated with pulmonary lesions, and 1 case of acromegaly. The first patient was a Polish woman, 28 years of age, with pleural exudate in the lower left thoracic region. The ends of the fingers, particularly those of the right hand, were clubbed and a trifle expanded, and the lower ends of the tibiæ were thickened and slightly tender. The second patient had suffered with a severe cough for some time, and showed a universal thickening of the metacarpal bones, particularly at their distal extremities. The feet were large and heavy, but the most remarkable feature is the great thickening of the lower thirds of the tibia and fibula. The third case was a farmer suffering from pulmonary tuberculosis who had similar lesions, and in addition had great enlargement of the lower ends of ribs and ulna. The enlargements of the wrist were associated with considerable pain of a dull character, aggravated by movement. The fourth case was a woman of 41. The changes of acromegaly had commenced about 10 years ago, with swelling of throat. Later there were shooting pains. Measurements made at intervals of two years showed in general a slight increase in dimensions of all the bones. Thorburn and Westmacott[3] record the postmortem appearance of one of their cases of hypertrophic pulmonary osteoarthropathy. The patient was a lad. Postmortem examination showed tubercular disease of the lungs, spine, the right tibia, and the right suprarenal capsule. There was almost universal symmetrical involvement of the bones and articulations—a form of osteoperiostitis of the limb-joints, with erosion of the cartilages of these joints. Thorburn looks upon the condition as probably a diffuse but mild form of tuberculosis of the bones. He thinks the theory of Marie, that it is due to

[1] Gaz. de Hebdom. de Méd. et de Chir., Feb. 16, 1896.

[2] N. Y. Med. Jour., Jan. 11, 1896.

[3] Brit. Med. Jour., May 30, 1896.

absorption of ptomains, unsatisfactory. He also considers the theory of Bamberg, that it is due to venous congestion, unsatisfactory.

BRONCHITIS.

Sokolowski[1] reports 4 interesting cases of **acute fibrinous bronchitis,** and concludes that the disease is purely an infectious disease, probably caused by infection with the staphylococcus albus and aureus. The so-called chronic fibrinous bronchitis is probably entirely different etiologically from the acute form, in which pulmonary tuberculosis appears to play a subordinate part.

Claisse[2] reports a case of **chronic membranous bronchitis** in which streptococci were found in cover-slip preparations and on the surface of the membrane, probably coming from the saliva. The condition had lasted for some years and was constant. After the discovery of streptococci Marmorek's serum was used, and in two months the patient was discharged, much improved, expectoration having almost ceased. There was a distinct reaction to the serum. [The report is not convincing, either as proving the relation of the microorganisms or as showing the advantage of the treatment employed.]

C. Gerhardt[3] reports an interesting case of a young baker who suffered with pain in the side, cough, and dyspnea, followed by expectoration of milk-like character which showed the presence of starch when tested with iodin. Physical examination of the lungs showed some disturbances of the respiration at the right apex and rustling rales below. The patient continued to expectorate **sputa containing starch** during $2\frac{1}{2}$ weeks after stopping his work, though the most careful cleansing of the mouth and pharynx was practised, and applications of iodin failed to determine the presence of starch in these parts or in the larynx. The author suggests that the condition was comparable to that occurring in persons who inhale **dust** in their occupations and expectorate sputa containing abundant dust-particles. He suggests that the asthma of millers and bakers may be due to the inhalation of flour and to its adhesive property. He found starch in the sputa of 3 bakers since the case reported came under his observation.

Stricker[4] discusses cirrhotic **atrophy of the mucous membranes** of the respiratory system, and reports 3 cases in which this was associated with the evidences of hereditary syphilis, which he considers of considerable etiologic importance; of these, 3 were remarkable for the fact that they suffered from albuminuria, either chronic or cyclic in type.

Sainz[5] divides **senile bronchitis** into four classes: ordinary chronic bronchitis, putrid bronchitis, bronchitis with gangrene, and bronchopneumonia. The most common microorganism associated with these appears to be the

[1] Deutsch. Arch. f. klin. Med., Mar. 26, 1896.
[2] Compt. rend. de la Soc. de Biol., Apr. 3, 1896.
[3] Centralbl. f. innere Med., May 16, 1896.
[4] Deutsch. Arch. f. klin. Med., Bd. 57, Heft. 1 and 2.
[5] Gaz. Hebdom. de Méd. et Chir., Jan. 12, 1896.

staphylococcus, although the streptococcus and the coli bacillus are also frequently found. He concludes that the bronchial mucous membrane is peculiarly susceptible in the aged, and to prevent, as far as possible, infection, he urges rigid hygiene in asylums.

Seifert[1] records an interesting case of **tracheal and bronchial stenosis.** The patient, a man of 43, had begun to suffer with difficulty of breathing a year previous, and finally respiration became almost impossible. When the patient came under the author's attention the laryngoscopic examination showed a moderate stenosis of the trachea at about the level of the third tracheal ring, and a more distant stenosis just above the bifurcation. There was also narrowing of the left bronchus. The treatment instituted was dilatation with suitably adjusted bougies, and the patient was eventually discharged in a much improved condition.

Duret[2] details a case of **bronchiectasis** in which recovery occurred after 3 operations. The patient, a girl, had suffered with the first symptoms after an attack of whooping cough at 8; at 18 the symptoms became pronounced, and at 21 the expectoration had become fetid and there was dyspnea. Three operations were done: first, aspiration with the trocar; then resection and evacuation through an opening made with the thermocautery; the third operation, 9 months later, consisted in the evacuation of other cavities with drainage; finally, the external wound was closed, and 2 years later the patient was in excellent health.

Treatment.—Thomson[3] in discussing the treatment of acute bronchitis declares that expectorant cough should be permitted as much as possible, and never suppressed. Irritating cough, on the other hand, demands sedative treatment. When both forms of cough coexist sedatives are indicated, but not in sufficient quantity to check expectoration.

Wessinger[4] advocates the use of **creasote** in the form of oleocreasote and of the carbonate in the treatment of bronchitis, gastrointestinal disorders, and tuberculosis. In the last-named affection the carbonate is preferable; in the others, the oleocreasote. The dose is practically unlimited so far as toxicity is concerned, but small doses are preferable—at the start 2 to 3 drops after eating. Glycerol forms a useful vehicle.

Chaplin[5] advocates the treatment of fetid expectoration by the **vapor of coal-tar creasote.** The value depends upon the penetrating, irritating, and antiseptic qualities of the drug. The method of application is to fill a small airtight chamber with the vapor of creasote, usually by boiling it over a spirit lamp, and then to place the patients in this chamber for as long a period as they can endure the treatment (a half hour being the maximum at first), but later they are able to endure it for an hour or more.

PNEUMONIA.

Etiology.—Finkler [1] contributes most interesting studies of the relation of streptococci and influenza bacilli to inflammatory process of the lungs. He has observed in previous epidemics, as well as recently, forms of pneumonia which he regards as due, for the largest part, to streptococci, and which are characterized by a more or less definite clinical course. The same organism is of the greatest significance in the pneumonias attending chronic tuberculosis of the lungs. The onset of the inflammation is rarely marked by a distinct chill; rigor and flashes of heat, alternating, are more frequent, and profuse sweats are often observed. The cough and pain in the side may be present from the start; the patient most frequently remains unaware of the infection of his lung. The physical signs are likely to be irregular; partial dulness, bronchial breathing, and moist rales are most prominent. Anatomically and clinically the process is a lobular pneumonia. Postmortem there is discovered serous and cellular exudation in the air-vesicles and alveoli. Fibrin-formation is rare. While in previous epidemics he has found this a highly malignant as well as a contagious affection, commonly ending in death, of late he has found it more benign, and he has even observed cases like those of Wassermann in which the course was chronic. The latter are sometimes distinguished from tuberculosis of the lungs with difficulty, but the more irregular course, the more extensive inflammation of the lung, and the less marked tendency to softening are suggestive points of distinction.

Kennan [2] reports 3 cases of pneumonia in which the early occurrence of irritability of the muscles overlying the affected part of the lung was demonstrable. In another instance the condition was bilateral in a case first thought to be pneumonia, but afterward found to be tuberculosis. He refers to the fact that such irritability leading to fibrillary contractures on striking the side is well known in phthisis, but thinks it may be a useful point in the early recognition of pneumonia. [In a recent case one of the editors found marked irritability of the thoracic muscles for several days before the physical signs developed. The muscular tenderness accompanied neuralgic pain of the affected side.]

Smith [3] reports the **statistics** of 223 cases of pneumonia; 170 were males, with a mortality of 28%; 53 were females, with a mortality of 31.2%. The mortality increased very rapidly with age, varying from none below 10 years to 40.6% in those of 50 years and upward. Rheumatic diathesis did not seem especially unfavorable; diabetes, however, was an exceedingly serious complication. In 144 cases in which an initial chill occurred the death-rate was 34%; in those in which it was absent it was but 19%. Affection of the right lung was more serious than that of the left in the proportion of 29.8% to 25.5%. When both lungs were affected the mortality was 48.7%. The degree of fever seemed to have no influence unless 105° was passed, when the mortality

[1] Infectionen der Lungen durch Streptococcen und Influenzabacillen, Bonn, 1895.
[2] Dublin J. M. Sc., Feb., 1896.
[3] Med. Rec., May 9, 1896.

increased rapidly. The highest degree of leukocytosis that occurred in 8 uncomplicated cases was 41,000. In 1 case in which empyema developed the count was 54,500. A severe initial chill and rapid, feeble pulse are regarded by Smith as indications of severe infection, and he considers the second sound at the pulmonic cartilage as the most valuable factor in the determination of the course of the case.

Powell [1] opened an interesting discussion upon pneumonia before the British Medical Association. He collected and tabulated statistics which show that though the death-rate from zymotic diseases generally has decreased in the last decade, pneumonia still holds its own. The disease is particularly baneful in attacking and destroying mature persons, one-third of the deaths occurring in adults. Regarding the causation, he concludes that the Fränkel diplococcus is only one among several microorganisms having claims to being the specific cause. It is found in other conditions as well, and is met with in certain secretions in health. Predisposing influences have lost none of their old time significance. He offers an interesting table showing the elements of danger and the methods of meeting these:

Elements of Danger in Pneumonia.

Symptomatic.	Pathologic.	Effects.	Treatment.
High fever, above 104°	Microbic activity	Shock.	
	Exhausted nerve centers		Bathing; quinin.
		Sleeplessness	Morphin preceded by accumulative stimulants and food.
Pain	(1) Over-distention of capsule of lung from exudation and hyperemic swelling.	Nervous exhaustion.	Leeches; ice-applications.
	(2) Pleurisy		Blister + hot poultices (except very young and very old persons).
Rapid pulse (120) and breathing (40)	(1) Impaired pneumogastric innervation.		Strychnin, caffein, atropin.
	(2) Impaired nutrition of heart from insufficient and badly-aerated blood supply.	Cardiac failure	Oxygen-inhalations (earlier employment).
	(3) Over-distended right cavities		Stimulants.
	Depleted left cavities		Digitalis and strychnin; bloodletting, local or general portal depletion.
Extending physical signs.	Extending exudation.		Acid tonics, perchlorid of iron, after fifth day; oxygen-inhalations (later employment).

The discussion following the paper was full and interesting, but cannot be satisfactorily summarized in this place.

Stienon [2] finds that, as a rule, the **increase in the leukocytes** in pneumonia disappears with the increase in fever. In the febrile stage the polynuclear forms predominate, but as soon as these begin to diminish the eosinophiles begin to increase. This increase occurred early in mild cases.

Complications and Sequels.—Vogelius [3] reports 2 cases of croupous pneumonia in which arthritis occurred. In the first the right sternoclavicular articulation became involved on the fifth day, and seropurulent liquid containing diplococci was removed. In the second case there was first empyema fol-

[1] Brit. Med. Jour., Nov. 9, 1895. [2] La Presse méd., July 13, 1895.
[3] Arch. de Méd. exper., Mar., 1896.

lowed by involvement of the hip-joint. This contained pus, and on examination diplococci, apparently identical with the microorganisms of Fränkel, were found.

Ruge[1] reports 2 cases in which **relapses** occurred in croupous pneumonia, and cites 7 others. The relapses usually occur after an afebrile period of from 4 to 15 days, during which time the symptoms are those of convalescence. The physical signs disappear, at least partially, and in the relapse reappear in the same place as in the first attack, or portions of the lungs previously unaffected may be involved. The duration of the relapses is from 4 to 8 days. Wandering pneumonia differs in its longer course, but transitional cases no doubt occur.

Dickinson[2] states that in 360 cases of pneumonia he has found **thrombosis** outside the heart in only 7 cases. Of these, 4 were young women and 3 were chlorotic. He further reports 3 fatal cases of thrombosis of the cerebral veins and sinuses in chlorosis. He believes that the occurrence of thrombosis in these channels is partly due to the fact that the cerebral venous blood is very slightly carbonized. It is of course also partly due to mechanic conditions. The lesser degrees of sinus thrombosis are not necessarily fatal, and he believes it more frequent than has been believed. In the discussion following the paper 2 fatal cases were reported by Duckworth, and Spurrell and Buzzard referred to cases.

Guinon and Bereau[3] report 2 cases of **subcutaneous abscesses** developed in the course of pneumonia. In both cases there had been slow resolution, then purulent pleurisy requiring resection of the ribs. Hypodermics of benzoate of caffein were given, and abscesses formed. These contained exclusively the pneumococcus.

Zuber[4] reports a case of pneumonia in which an abscess containing pneumococci in pure cultures developed at the site of a hypodermic injection.

Treatment.—Glass[5] has subjected **Sziklai's pilocarpin-treatment** of pneumonia to a careful test, and concludes that the administration of the drug in doses of 1 or 2 cgm. produces serious symptoms of collapse, and results in some cases in the rapid extension of the pneumonic process. A pronounced cure was never established. In delayed resolution, however, the remedy can be administered in these doses without producing unfavorable symptoms, and may effect a rapid solution of the pneumonic infiltration. [Our own experience with pilocarpin in cases in which pulmonary disease was present has coincided with that of Glass, and we should therefore hesitate to use the drug in pneumonia.] Sziklai[6] vigorously supports, against the criticisms of Glass, his original contention that pilocarpin is a specific, in the widest sense of the word, against all croupous diseases (those associated with a fibrinous exudate), curing laryngitis crouposa in a few hours and croupous pneumonia in from 2 to 3 days. He insists upon large doses, 8 to 10 cg. a

[6] Wien. med. Woch., Jan. 18, 1896.

day, and denies that symptoms of collapse or other injurious action occurs. Heart-disease he admits to be a contraindication. Particularly in pneumonia with delayed resolution, as Glass himself admits, are the results of the daily administration of 1 to 2 cg. excellent. Unless the condition be very urgent Sziklai prefers administration by the mouth. Liszt[1] has treated 46 cases of pneumonia with pilocarpin after the method of Sziklai. The treatment was strikingly favorable in its results, the patient soon becoming quieted and the respirations becoming regular, and in the majority of cases the crisis ensuing after intense perspiration; the temperature, however, did not sink below normal at once. The degree of sweating is quite variable in different cases, and appears to be indifferent in this significance. The treatment exercises an immediate and progressive action upon the condition of the lungs, and in cases in which it has begun early resolution at once occurs, so that complete hepatization may never occur. Poulet[2] reports 108 cases of pneumonia following grippe, with 4 deaths, all being treated with pilocarpin hydrochlorate, as much as $\frac{5}{6}$ gr. being given at once.

Naegeli-Akerblom[3] used the fluid extract of **digitalis** according to the method of Petresco in 64 cases of pneumonia. Of these, 11 were fatal. Under 4 years of age not a single person died of pure croupous pneumonia; and of 9 fatal cases between the ages of 50 and 90 years, 7 were hopeless from the beginning. The shortest period in which the crisis occurred was 3 days. He concludes that in large doses digitalis increases the leukocytes, especially the polynuclear cells. Daily doses of 4 or 5 gr. are borne without injury.

Corin[4] has employed **digitoxin** in the treatment of pneumonia. He reports 26 cases that he observed very closely, and in which he systematically used the drug from the first visit; 2 of these died—1 who also suffered from extreme emphysema, and 1 that was moribund when the treatment was commenced. The duration of the disease after treatment was commenced was from 24 to 36 hours. The usual dose is about $\frac{1}{20}$ gr. in solution of chloroform and alcohol, taken in 3 parts at intervals of 6 or 8 hours. No unfavorable symptoms or cumulative action was ever noticed.

Edema of the Lungs.—Huchard,[5] referring to acute edema of the lungs, comments upon the gravity of this condition, and holds that it is due to disturbances of the cardiopulmonary innervation, to excessive pulmonary tension, and to sudden failure of the right ventricle. The best treatment is venesection from the arm, wet-cupping over the chest and liver, and subcutaneous exhibition of caffein, but, above all, of camphorated oil (1–5); 3 or 4 Pravaz syringefuls a day may be injected; the injections are not painful. Strychnin may be useful, but morphin is dangerous.

Bishop[6] commends very highly a large **thick jacket-poultice,** either made in one piece or in sections large enough to envelop the whole chest, and thick enough to retain its heat for some time, for acute edema of the lungs.

[6] Am. Med.-Surg. Bull., Feb. 22, 1896.

Quincke[1] has tabulated 54 cases of **pulmonary abscess** treated by surgical operation. Of these, 17 were treated by the author, and he divides them into 3 groups: 1. Acute abscess, either simple or gangrenous; 2. Chronic abscess and fetid bronchiectasis; 3. Suppuration caused by a foreign body. In 83% of the 54 cases the lower lobe was the seat of the disease; 20 patients died, 20 recovered, and in 14 there was either failure or imperfect result. The mortality was about the same in acute and in chronic cases, but complete recovery is much more common in the acute cases, the chances of success being placed at 66%. He objects to exploratory puncture for diagnosis, as infection of the pleuræ may occur.

Lemaistre[2] discusses the **chalicosis** of workers in porcelain. He finds that the color imparted to the sputum is not due to pigment of hematogenic origin, but rather to the impregnation by particles of carbon, such as are found in all factories. In conclusion, he urges careful hygiene upon the part of the manufacturers, indicating that ample space and free ventilation are essential.

Actinomycosis.—Heusser[3] reports a case of primary actinomycosis of the lungs. The patient, a woman of 50, became ill with fever, showing elevations in the afternoon and with signs of right-sided pleurisy. Aspiration was practised, with the discovery of 600 c.cm. of clear pleural fluid. The apices were uninvolved; the sputa were small in amount and contained no tubercle bacilli. The general health declined slowly, and after some months the patient was removed to Davos. At this time infiltration of the right upper lobe and cavity-formation in the right lower lobe with pleural thickening were diagnosed, and the greenish yellow sputa contained actinomyces granules, but no tubercle bacilli. The patient's condition improved, and the evidences of consolidation and of excavation subsided, when she passed from observation.

Renon[4] reports 2 cases of pseudotuberculosis due to the aspergillus fumigatus. This occurred in a man and his wife who were engaged in combing and sorting hair. When the hair was moist rye-flour was used to dry it, and a good deal of dust was caused in the work. The wife was taken with hemoptysis after having worked for 7 years, and had the signs of an early tubercular lesion in the left lung. The husband was taken 9 years after he began the work with violent attacks of hemoptysis, and had signs of a cavity in the left lung with general bronchitis. In neither case did the sputum show tubercle bacilli, but there was much mycelium, and culture-experiments showed the aspergillus fumigatus. Of 6 pigeons subjected to inhalations of the dust of the room, 5 died promptly with lesions of aspergillus infection. The 6th recovered, but showed healed lesions at a subsequent autopsy. Renon thinks that millers and all other workers with grain are liable to contract the disease, and cites the aspergillar keratitis that occurs in millers.

[4] Compt. rend. de la Soc. de Biol., Nov. 1, 1895.

Schmidt[1] has reported 3 cases in which **protozoa** (Trichomonas) occurred in the sputum. The first was a case of aspiration-pneumonia following cancer of the larynx. There was slight bronchiectasis. The second was one of probable bronchiectasis in chronic pneumonia and pleurisy. The third was one of long standing bronchiectasis. Protozoa were found only in "Dittrich's plugs." Their size was that of a pus-corpuscle; they were oval in shape and granular. At one end 1 to 4 flagella in active motion were found, and extending back along the body was an undulating membrane. The body ended in a pointed tail. The author suggests the name *Trichomonas pulmonalis*, though he admits it may be the same species as that found in the vagina. The organism could not be cultivated.

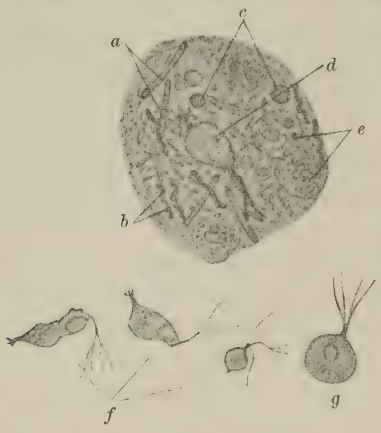

FIG. 2.—*a*, large bacilli; *b*, spirilla; *c*, fat-drops; *d*, Trichomonas; *e*, pus-cells; *f*, different forms of Trichomonas; *g*, dying form (Münch. med. Woch., No. 51, 1895).

Pulmonary Neuroses.—Marcet[2] in his Croonian Lectures refers particularly to asthma in a clinical way. He points out that in coughing there is first a long breath, followed by the paroxysm of coughing, and this in turn by a deep breath to supply the blood with fresh oxygen after the forced expirations of the cough. Further, he points out that asphyxia occasionally produces spasms of the glottis, as in some cases of recovery from drowning, and expresses the belief that in some cases the momentary want of air produced by a bad fit of coughing may similarly be the cause of spasmodic asthma in persons subject to it. He refers to a physician subject to asthma who had a severe attack of wheezing and tightness of the chest after taking a cup of tea in the early morning. A succession of forced inspirations had the immediate effect of arresting both the wheezing and the tightness, and a second attack the same night was averted in a similar manner. He believes that asthma may be due to an excess of carbon dioxid in the body, and recalls the fact that the attacks set in with sudden cough, coming on in the evening or at night, and followed by spasm of the bronchial system. Subsequently the respiratory muscles become fatigued from overexertion at inspiration, and this further impediment prevents oxygen from reaching the centers of respiration. He therefore advocates measures to strengthen the respiratory muscles, and in particular recommends bicycle-riding. Regarding the latter, he cites the case of one person observed by himself in whom the paroxysms became much fewer, and finally almost ceased, after resort to this mode of exercise.

Strubing[3] reports a series of cases illustrating respiratory neuroses. In 2 cases there were attacks of slow and deep breathing, with subjective feeling of

[1] Münch. med. Woch., No. 51, 1895. [2] Lancet, June 22, 1895, et seq.
[3] Zeit. für klin. Med., Bd. xxx. H. 1 and 2.

dyspnea and anxiety, and in 1 case orthopnea. The author terms this condition **spanopnea,** regarding it as an inhibitory neurosis. The cause in one case seemed to be irritation of the respiratory inhibitory fibers of the superior laryngeal nerve in swallowing; in the other it seemed to be an asthma from irritation of the trigeminal fibers in chronic rhinitis. He also reports 2 cases of tachyopnea in which paroxysms of increased frequency and diminished depth of the respirations occur. One of these cases ceased after restoration of a retroflexed uterus. The other case was purely neurotic in character.

PLEURISY.

Aschoff[1] has studied 200 cases of serous pleurisy in Fränkel's ward to determine the **bacteriologic relations** of this affection. Cultures were made upon agar; fresh stained preparations were examined, and in 20 cases intraperitoneal inoculations were made in white mice; 43 of the 200 cases were found to be tuberculous by the discovery of tubercle bacilli in the sputum or other products; 19 others gave a tuberculous history. Direct bacterial examination gave positive results in only 7 of the 200 cases, and out of 17 inoculations only 2 belonging to the 7 cases with tuberculous history gave positive results. These were the cases of sepsis, and 1 of tuberculosis. The others were—metapneumonic 2, idiopathic 2, and 1 of each showing streptococci, and 1 pneumococci; 1, following gangrene of the lung, with streptococci. In the remaining 193 cases bacteriologic examinations were negative, and these the author divides into 2 groups, the first giving evidence of tuberculosis or a suspicion of this, and the second, so called idiopathic cases. Of 13 belonging to the first class, inoculations in guinea-pigs gave positive results in 7. Of inoculations in 12 suspected cases, 3 were negative. Among the so called idiopathic cases, 9 out of 12 caused tuberculosis in guinea-pigs. The author concludes that the view that most cases of idiopathic pleurisy are tuberculous is considerably strengthened by his observations; such cases may recover completely. He doubts whether rheumatic pleurisy ever occurs without affections of the joints or the heart, and in 16 cases in his series complication upon the part of the heart was invariably present. As regards the question of serous exudation and pathogenic bacteria, he concludes that such exudates are almost always free of bacteria, but if pyogenic organisms are present, suppuration is likely to occur, though in the case of pneumococci the early death of the organisms prevents the termination in suppuration.

Lefevre[2] has endeavored to determine the **etiology of pleural exudates,** and has been surprised at the rareness with which positive results were obtained in experiments made to determine the proportion of tubercular pleurisies. He found, however, in studying his cases, that many of them were preceded, accompanied, or followed by well marked rheumatic symptoms. Of 18 probably rheumatic pleurisies, 10 ran the course of simple fibrinous pleurisy without serous effusion; 3 were fibrinous at first, with subsequent effusion; and in 5 effusion existed from the commencement.

[1] Zeit. f. klin. Med., Bd. xxix. p. 440.

[2] Med. Rec., Feb. 8, 1896.

Charrin and Nobecourt[1] report a case of pleurisy developing in a woman 7½ months pregnant. The fluid withdrawn was purulent, and contained gas and a bacillus identical with the proteus vulgaris.

Levy[2] reports a case of **pneumothorax following pleurisy.** An anaerobic gas-producing bacillus was found in the exudate. At the autopsy there was no sign of perforation, the condition being one of spontaneous pneumothorax.

Faitout[3] contributes a collective paper regarding the **gonorrheal origin** of pleurisy. He finds a good number of reported cases, but only 1, that of Bordoni-Uffreduzzi, in which Mazza made the bacteriologic examinations, seems definitely established.

West[4] reports an interesting case of serous or albuminous expectoration after **paracentesis for pleural effusion.** The patient was a man of 40; he had had right-sided effusion for 3 or 4 weeks; 40 ounces of fluid were drawn with a siphon, when cough and distress occurred. Ten minutes later expectoration began, and in an hour 8 ounces were discharged. The attack lasted 3 hours, during which time a pint of frothy liquid was coughed up. Much wheezing and crepitation occurred in the chest, especially on the affected side. In studying the history of cases of this kind he found much difference in the different cases. The duration is usually not more than an hour or two, though extreme limits of 48 hours have been reported. The fluid varies from a few ounces to 3 pints, and contains much mucin and little albumin. The physical signs are those of congestion of the lungs. As a rule, serous expectoration occurs in cases in which the effusion is tapped late in the case. The result is rarely fatal, and among the fatal cases some complication was generally found. The only tenable explanation is that effusion is due to edema of the lung. In the discussion Hale White stated that he had recently seen a case in which the patient expectorated large quantities of liquid after aspiration. A striking feature was the fact that the condition lasted for several days.

Diagnosis.—Kellock[5] describes **a new physical sign** in pleural effusion. The observer stands at the left side of the patient and places the left hand flat and very firmly on the lower part of the thoracic wall just below the nipple, percusses sharply either with a finger of the right hand or with a pleximeter on the ribs of the same side, striking them just posterior to the angles. If no fluid be present, a very slight vibration of the rib which is struck posteriorly is felt by the left hand in front, or if there be fluid in the pleural cavity the vibration of the rib is much greater. If the quantity of fluid be considerable, the difference between the sensations experienced by the left hand when examining the sound or affected sides is most marked. He was able to obtain this sign even in cases in which the amount of liquid was small.

Pitres[6] calls attention to what has been designated a **plumb-line sign**

[1] Compt. rend. de la Soc. de Biol., June 21, 1895.
[2] Arch. für Exper. Path. und Pharmakol., Bd. xxxv. H. 4 und 5.
[3] Gaz. de Méd. de Paris, Oct. 5, 1895.
[4] Brit. Med. Jour., Apr. 18, 1896.
[5] Lancet, Mar. 28, 1896.
[6] Arch. clin. de Bordeaux, Feb., 1896.

(*signe du cordeaux*) of pleural effusion. The increased size of the chest on the affected side and the inspiratory position of the lower ribs cause a rotation of the sternum, the center of rotation being the top and the radius the entire length of the sternum. In consequence the plumb-line dropped from the middle of the sternum above would be from 2 to 4 cm. away from the sternum below. In measuring the size of the chest on each side with the cyrtometer the measure in front should be from this line, and not from the middle of the sternum. The fact that other conditions produce similar results make this sign comparatively of little value.

Bargebuehr[1] discusses **chylous exudates** into the serous cavities. He first reports a case in which there was secondary carcinomatous infiltration of the thoracic duct, following carcinoma of the stomach without chyloric effusion. He then reports 2 cases that he observed in which chyle or a chyliform liquid was found in the pleural cavity—1 a case of carcinoma of the peritoneum with metastasis to the liver, left lung, and pleura; 1 a case of carcinoma of the stomach with metastasis to the lymphatics of the lungs and to the liver. In the first case the liquid appeared to be of the nature described by Quincke as hydrops adiposus; in the second case the liquid contained sugar and was probably chyle. He now investigated the subject as presented in literature, and finds that altogether 41 cases have been recorded during a number of years. Some of these cases, however, are exceedingly doubtful, the absolutely certain cases being 5 in which there was a gross lesion of the lymphatic vessels; 1 in which filaria existed; 5 in which the liquid had been recognized by chemical analysis; 11 other cases may possibly be purely chylothorax. The remaining 11 cases may be included under the term hydrothorax chyliformis or adiposus. Regarding the diagnosis of the condition, it can be made only by the abstraction and analysis. There are no characteristic symptoms, either urinary or other. The prognosis is not favorable. Of 22 cases, 17 died; 4 were cured and 1 remained unimproved. The treatment is purely symptomatic, and paracentesis should be delayed as long as possible, because the pressure of the liquid tends to hinder the outflow of the chyle. In conclusion he calls attention to Hausenbrock's unique case of chylopericardium.

Hale White[2] contributes a report of **empyema** following lobar pneumonia. The report includes 26 cases of metapneumonic empyema that occurred within the last 10 years. The mortality was near 30%. Among the fatal cases were some in which general sepsis and malignant endocarditis occurred. Spontaneous cure occurred in 1 case by perforation through the lung; in all of the other cases operation alone effected a cure, mere aspiration being insufficient.

Pneumothorax.—Levy[3] reports an interesting case in which **gas** developed spontaneously **in a pleural exudate.** The patient, a man of 48, had been aspirated 5 times for a pleural exudate of serous character. A week after

[1] Deutsch. f. klin. Med., July 18, 1895.

[2] Guy's Hospital Reports, Lond., Perry and Jacobson, 1895.

[3] Arch. f. Exp. Path. und Pharmakol., xxxv., 1895, 4 und 5.

the last operation pneumothorax developed. Aspiration, and finally resection of a rib, were practised, but the patient died. At autopsy a caseous focus was found in the lung, and miliary tubercles on the peritoneum. There was no perforation of the pleura. Cultures made at the last operations showed the presence of a thick and immobile bacillus which caused abundant gas-formation, and was pathogenic for guinea-pigs. It is anaerobic, and corresponds to organisms found by the author in a parametric gas-abscess, and by Fränkel in several cases of gas-phlegmon.

Unverricht[1] considers the **treatment of tuberculous pneumothorax.** He recommends the establishment of the thoracic fistula large enough that air may enter freely and thus permit the pulmonary fistula to heal. The author applied this method in 2 cases within the last year, and found that it not only served to save life, but led to a repair of the pneumothorax. In 1 case recovery ensued after 14 days; in the other case the patient died, but there had been progressive diminution in the pneumothorax.

Intrathoracic Tumors.—Wolf[2] reports 31 cases of primary **carcinoma** of the lung occurring in over 7000 autopsies; 27 of the patients were men and 4 were women. The youngest was 36 and the oldest 70. The right lung was affected 5 times, the left lung 3 times, the right bronchus 13 times, the left bronchus 8 times, and both bronchi were involved twice. In 13 of these cases tuberculosis was a complicating condition. Metastasis was more likely to occur when the primary tumor affected the bronchi than when it affected the lung.

Ribbert[3] reports a case of carcinoma of the lungs that, besides spreading along the lymphatic channels, also entered the air-passages and spread along the surface of the alveoli until almost the entire lung was involved. He concludes that it is justifiable to believe that the carcinoma originated from the epithelium, and is to be considered as a primary tumor.

Pepper and Stengel[4] discuss the subject of intrathoracic tumors, particularly their clinical manifestations. Regarding the nature of the tumors, they first take exception to the statistics of Steinthal's and Hare's monographs, believing with Fagge and Powell that carcinoma is an exceedingly rare form. Of their own cases, 6 are sarcomata, 1 secondary cancer, and the other 2 probably sarcoma, although the specimens had been lost. Regarding locality, tumors of the anterior mediastinum are found to be three or four times as common as those of the posterior mediastinum. They usually arise from the remnant of the thymus, less commonly from the lymphatic glands. The tumors of the pleura, when primary, are usually endotheliomata, and of the lung carcinomata. Clinically the tumors are classified according to their situation in the posterior, middle, and anterior mediastinum. Of the first two divisions the subjective symptoms are of most importance, while tumors of the anterior mediastinum usually are easily recognized by the physical signs. An interesting case of this character is reported in which there was edema of the face and neck, considerable dyspnea, and at the autopsy a round cell sarcoma was found surrounding the base

[1] Centralbl. f. innere Med., Apr. 25, 1896.
[2] Fortschr. d. Med., Nos. 18 and 19, 1895.
[3] Deutsch. med. Woch., 1896, No. 11, p. 365.
[4] Internat. Med. Mag., Nov., 1895.

of all the large vessels and extending backward from the bronchi. The tumors of the middle and posterior mediastinum have, as their most decided symptom, dyspnea, which may increase to the highest degree of orthopnea. In some cases there is also dysphagia. Fever often occurs, particularly in growths of the posterior mediastinum. In regard to diagnosis the symptoms are usually extremely irregular, and resemble those of aneurysm, the most valuable distinction being the tendency on the part of intrathoracic tumors, particularly those of the anterior mediastinum, to cause early occlusion of the large veins, giving rise to enlargement of the superficial veins and other signs of venous engorgement. Tumors of the pleura are marked by more or less equally decided symptoms and physical signs.

DISEASES OF THE CIRCULATORY SYSTEM.

DISEASES OF THE PERICARDIUM.

Ewart[1] contributes a valuable article on **diagnosis of pericardial effusion.** Among the points are the following: extension of the lateral boundaries of the total area of dulness and great extension of the absolute dulness, the sternum being entirely dull; depression of the liver; dulness in the right fifth intercartilaginous space; and alteration of the lower angles of the triangle of cardiac dulness. The right angle, instead of projecting vertically downward or incurving toward the sternum, projects obliquely outward, and in this way furnishes a distinction from cardiac dilatation. The left angle is of importance, especially with regard to its position as related to the position of the apex-beat. Regarding the latter Ewart points out that the text-books are uniformly in error in alleging that the apex is elevated sometimes as high as the 3d rib by the accumulating effusion. The pulsation seen in this position is not the apex, but rather the base uncovered by the displacement of the lung. The author showed by preparing liquids of the specific gravity of the usual pericardial effusion that this could have no effect in the way of elevating the apex. Some slight upward displacement, he holds, may take place by the distention of the sac and the consequent upward dislocation of the bronchi, and with them of the pulmonary veins and heart; but this rise must be inconsiderable, and as a matter of fact he has found a descent of the apex. Further, he calls attention to the hyperresonance of the upper part of the chest due to relaxation of the lung and to the bulging of the left chest. A sign of considerable interest is that designated **"the first rib sign"** which he has found in all cases of considerable effusion. He finds that it is possible to feel with the finger the upper edge of the 1st rib as far outward as the sternum. The author thinks this especially connected with immobility and elevation of the lower ribs, coupled with great activity of the superior respiratory region of the chest. The left clavicle seemingly rises higher than is possible for the first rib. He has rarely seen this condition except in pericardial

[1] Brit. Med. Jour., Mar. 21, 1896.

effusion and some cases of considerable cardiac enlargement. The raising of the 1st rib is unlike that of emphysema, in which the rib and clavicle move together.

He calls attention to the patch of dulness immediately to the left of the spine and along the inferior margin of the ribs. Among the auscultatory signs is the occasional appearance of bronchial breathing below the right breast, which he regards as due to the active respiratory draught kept up by the movements of the upper lobe at the origin of the bronchi for the middle lobe, coupled with the consolidation of the latter in this situation. Posteriorly the breath-sounds are absent from the dull patch above described, and a rounded patch of tubular breathing has often been found below the angle of the scapula. Regarding the pulse, he states that he has frequently observed a large slapping pulse similar to the Corrigan pulse, though never so extreme. [Dr. Ewart's paper deserves careful study. He does not attempt to discuss systematically the well known signs of pericarditis, but rather adds certain novel ideas, and in this respect the paper is most suggestive.]

Broadbent [1] reports a **new sign of pericardial adhesions,** consisting of the visible retraction synchronous with the cardiac systole of the left back in the region of the 11th and 12th ribs. He reports 4 cases in which this sign was very marked, and in 3 of them it was present in a less degree also upon the right side. He believes that it is caused by a tug of the enlarged heart upon the central tendon of the diaphragm. In 3 of these cases there was also evidence of adhesion of the pericardium to the chest wall. In 1, however, the heart appeared to move freely beneath the ribs, and the area of cardiac dulness was diminished during inspiration, so that this constituted the only sign of pericardial adhesions.

DISEASES OF THE HEART.

Methods of Examination.—Gumprecht [2] advocates percussion of the heart with the patient leaning forward so as to bring the heart into close approximation with the anterior wall of the chest. In this position the boundaries of the normal heart are the left edge of the sternum, the 4th rib, and the left nipple line, or even beyond this. The width of the heart as compared with the circumference of the thorax is as 1 to 8. The advantage of the method is the greater ease of determining the outlines of the organ and the fact that emphysema and other conditions do not obscure the cardiac dulness. [We have used this method in a large number of cases, and have been able to convince ourselves of its value in a number of instances. In 1 case an aneurysm of the arch of the aorta was first detected in this manner.]

V. Basch [3] urges the more extensive use of the **sphygmomanometer** to determine the degree of arterial tension, and claims that even the most experienced clinicians differ or are uncertain in testing the pulse by the tactile method.

[1] Lancet, July 27, 1895. [2] Deutsch. Arch. f. klin. Med., Bd. lvii. p. 490.
[3] Wien. med. Woch., No. 15, 1896.

Robertson[1] calls attention to a considerable imperfection in the Dudgeon and Marie **sphygmographs**; that is, the irregularity with which the paper is passed under the style. The motion is usually most rapid at first, and then diminishes rapidly. He recommends that each instrument be marked with the ascertained velocity of its movement. Tracings are given to show the effect of varying velocities upon the pulse-tracing. The instrument should always be freshly wound up before each application.

Andrew H. Smith[2] holds that the **value of the differential stethoscope** lies in its use for determining the time rather than the quality of sounds heard in different cardiac localities, particularly when there is a murmur at the apex and another at the base, both occurring in the same period. It is also useful in detecting slight degrees of reduplication of the ventricular systole.

Auscultatory Percussion.—Broadbent[3] criticises adversely a paper of Dr. Thorne on the Schott method of treatment, calling attention to the fact that the latter found the cardiac dulness as far to the right as the nipple-line at the upper limit of the cardiac dulness. He holds this to be irreconcilable with anatomic or clinical experience. He criticises still more unfavorably the bipartite outline found at the base of the heart and ascribed by Thorne to the presence of the auriculoventricular fibrous ring. Broadbent points out that this notch falls exactly in the position in which the aorta and pulmonary artery are situated. [While we must agree with Broadbent that his criticisms are justified so far as the facts are concerned, we cannot agree that auscultatory percussion is an unreliable method. We have ourselves practised this method in very many cases as a means to determine the cardiac outline, and while we have obtained no such results as Thorne's, we still have found it most useful in determining the size and shape of the organ.] Thorne,[4] in reply to Sir William Broadbent's objections to the method of auscultatory percussion, declares that it is quite possible to distinguish between the impairment of resonance caused by the subjacent heart and the vessels respectively, and that it is then possible to produce bipartite outlines of cardiac dulness; he also insists that the position of the auriculoventricular fibrous ring may be demonstrated by his method.

Acute Endocarditis.—[A number of cases have been observed during the year that suggest the possibility of the gonorrheal origin of this disease. Bacteriologists have shown that the gonococcus is capable of producing various metastatic lesions, and it seems practically certain that endocarditis may be one of the possible results.]

Winterberg[5] reports a case of acute endocarditis occurring during the course of an attack of specific urethritis which was complicated by right-sided epididymitis and enlargement of the glands in the groin. No improvement

[1] Edinb. Med. Jour., Mar., 1896.
[2] Med. Rec., July, 1895.

occurred after the administration of sodium salicylate. At the autopsy numerous purulent foci were found in the myocardium, and the aortic and pulmonary leaflets were almost entirely destroyed, being represented only by fibrous, friable, caseous remains. Microscopic examination of the cardiac valves showed the presence of diplococci having the appearances of gonococci. [The absence of culture-experiments renders this case somewhat uncertain, but the following seems more definite.] Thayer and Blumer [1] report the case of a female of 34 who entered the hospital complaining of cough, weakness, and general pains. Her illness dated from an attack of rheumatism which occurred 3 months before, and in which most of the joints were affected, the disease passing rapidly from one joint to another. The day previous to the admission there was a chill. On examination enlargement of the heart with a presystolic and systolic murmur at the apex and an accentuated second sound at the pulmonary area were discovered. She lived 19 days, showing during this time irregular exacerbations of temperature, often attended with chills and marked emaciation. The spleen was palpable and there was considerable anemia. Acute ulcerative endocarditis of the mitral valve with infarcts in the lungs and spleen was discovered postmortem. Cultures from the blood during life on a mixture of blood and agar showed growths of the appearance of gonococci, and the organisms corresponded in their staining reactions (Gram's method) with gonococci. Cover-slip preparations made at the autopsy from the vagina, uterus, and vegetations on the mitral valve gave similar results, but cultures failed, and a mouse inoculated with a portion of the vegetation remained unaffected. [It seems likely that this case was one of true gonorrheal endocarditis.] Hale White reports a case that entered the hospital suffering from chill and hectic temperature. Subsequently a fine diastolic murmur was heard over the pulmonic cartilage, and later also a faint systolic murmur. All the symptoms of septicemia appeared, anemia grew profound, and there were attacks of uremic dysentery, in one of which the patient died. The only etiologic factor was an attack of gonorrhea contracted four weeks previously to admission. Examination of the blood for the gonococcus was fruitless. At the autopsy the pulmonary valve was found to be extensively affected with recent malignant endocarditis, and in the vegetations an organism resembling the gonococcus in appearance was found.

Zawadski and Bregman [2] report a case of acute endocarditis with embolism of the Sylvian artery which they regard as gonorrheal in origin. The case was a girl of 17 years who was admitted to the hospital with signs of cardiac disease, the heart being enlarged and the presystolic murmur being determined at the apex. Paresis and later paralysis of the right side were detected, and enlargement of the liver and spleen were determined. There was a mucopurulent vaginal secretion, and the mucous membrane of the cervix was reddened. The history showed that the patient had been exposed to infection, having become an inmate of a house of prostitution a month previously. Cultures made from the discharge discovered the staphylococcus pyogenes

[1] Arch. de Méd. expér., Nov., 1895. [2] Wien. med. Woch., Feb. 15, 1896.

albus and micrococcus tetragenus. Gonococci could not be determined by the method of Turró. Subsequent bacteriologic examination showed the same microorganisms and also the streptococcus pyogenes. The patient suffered with hurried and irregular breathing, and died after 3 months' duration of the illness. There was marked irregularity of the temperature. The postmortem examination showed embolism of the Sylvian artery on the left side, with softening of the corpus striatum and part of the internal capsule; there were pleurisy, consolidation of the right lung, swelling of the spleen, and large white kidneys. Verrucose endocarditis of the mitral valves was discovered. Microscopic examination of the vegetations showed microorganisms corresponding to gonococci in their appearance and behavior to Gram's stain. Microscopic examination of the pleura was negative. No cultures were obtained.

Dauber and Borst [1] report a case occurring in a young man aged 20 years. Ten days before his admission to the hospital a purulent urethral discharge set in, and he came to the hospital on account of pain in the inguinal region. The urethral discharge contained diplococci corresponding to gonococci in their general characters. Fever developed, and after a month evidences of aortic valvular disease were obtained. The patient died 3 months after the onset of the gonorrhea. The postmortem examination was made 5 hours after death, and cultures were made with the blood and splenic pulp after the method of Král. The aortic valve was extensively diseased. Sections of the vegetations showed diplococci of biscuit-shape in and outside of the cells, and these were decolorized by Gram's method. Only 1 of the culture-tubes presented growths, and these were not of the character assumed by gonococci. The authors conclude that the endocardial disease was due to a microorganism resembling the gonococcus, but not identical. They regard the urethra or a small paraurethral abscess that existed in the case as the point from which infection occurred. [This case suggests the possibility that other instances of supposed gonorrheal endocarditis may have been caused by other microorganisms; but it is inconclusive. The organisms in the authors' case were not studied as thoroughly as could be desired. It is certain, however, that a diagnosis cannot be made from microscopic examinations alone. One of the editors (Stengel) reported a case before the College of Physicians of Philadelphia (the report has not yet been published), and held that the gonorrheal nature of his case could with some justification be assumed from the facts that micrococci corresponding in appearance and behavior to stains were found in the cardiac vegetations, and that cultures with ordinary media (agar, glycerin-agar) *failed* entirely. Suitable media for the cultivation of gonococci were not at hand.]

Caton [2] in a paper on the treatment of acute rheumatic endocarditis states that among 320 cases of **acute rheumatism,** endocarditis occurred in 20%, for the most part during the first 10 days of the disease, but sometimes not until defervescence or even a relapse had occurred.

Charrin [3] records a case of acute **endocarditis following tonsillitis.**

[1] Deutsch. Arch. f. klin. Med., Bd. lvi. H. 3 and 4.

[2] Lancet, Aug. 17, 1895.

[3] Semaine méd., Mar. 14, 1896.

The patient, a male of 18, had been at work up to within a few days before admission. When he entered the hospital his temperature was between 104° and 105° F. He had dyspnea, patches of consolidation in the right lung, enlargement of the liver and spleen, albuminuria, and weak heart-sounds. The right tonsil was moderately swollen. A diagnosis of bronchopneumonia secondary to tonsillitis, the latter originating in influenza, was made. The patient died. Postmortem the condition of the lungs was found as expected, while exuberant vegetations were seen on the pulmonary valves. The staphylococcus aureus was found in the vegetations; the same organisms had been found swarming on the tonsils. The author believes this to have been the source of general infection.

Leyden[1] contributes an interesting contribution to the subject of **tuberculous endocarditis.** After discussing the relation of tuberculosis to diseases of the heart in general, he alludes to 4 cases in his own experience of acute endocarditis in which tubercle bacilli were discovered in the vegetations. In 1 of these cases the bacilli were also present in antemortem clots in the heart. He points out that acute endocarditis in tuberculosis is not due to the tubercle bacillus, and he also draws attention to the fact that in the cases in which the bacilli were found they were found in the cells of the vegetation. It is thus evident that the bacilli may be transferred to other parts and set up foci of tuberculosis.

Blumer and Young[2] report a case of **anthrax septicemia** in which acute endocarditis occurred.

Symptoms.—Dock[3] reports a case of malignant endocarditis developing 3 weeks after delivery, in which the fever was intermittent and was at first supposed to be malaria. Later a slight painless effusion occurred in the right knee joint. The heart-beat was regular and there was a marked systolic murmur, loudest over the apex, with several systolic murmurs along the edge of the sternum. There was a slight leukocytosis, but no parasites or pigment in the blood. The fever lasted about 49 days, and was for the most part intermittent, the rise of temperature usually occurring about noon and reaching its acme about 5 P. M. Sweating was almost always present during the decline. Large masses of vegetations were found on the aortic and mitral valves, which contained numerous streptococci in short chains. He further reports 2 cases that had occurred previously in his practice, in both of which intermittent fever was present, and recent vegetative endocarditis was found upon valves already diseased.

Treatment.—Caton[4] discusses the treatment of rheumatic endocarditis, consisting in the administration of **potassium** or **sodium iodid** in 10 gr. doses 3 times daily, in addition to **salicylates** and the application near the apex of a small **blister.** This treatment is begun as soon as the bruit is perceptible, or even prior to that, during the stage of "woolliness." When the the irritation of the first blister has subsided he applies a second, then a third,

[1] Deutsch. med. Woch., Jan. 9, 1896. [2] Bull. Johns Hopkins Hospital, 1895, Nos. 54, 55.
[3] Boston M. and S. Jour., Nov. 7, 1895. [4] Lancet, Aug. 17, 1895.

and so on; at the same time keeping the patient quiet, forbidding exposure or too much nitrogenous food. In defence of the value of the blister he states that it is likely that reflex influences operating through the nervous system are conveyed from the exterior to the organs and structures underlying the point of application. He calls attention to the fact that chilling of the thorax may cause bronchitis or pneumonia, and that a splash of cold water excites respirations in an infant or sets the action of the heart going during a faint. Further, he refers to his previous discussion before the Physiological Society at Oxford, in which he showed that stimulation of the surface-skin alters the caliber of the arterioles in the lung and causes variation in the electrical condition of thoracic and abdominal organs.

CHRONIC VALVULAR DISEASE.

Jackson[1] discusses the postmortem examination of 100 cases of cardiac disease. He finds that the lesion which most frequently escaped observation was the aortic disease combined with insufficiency of the mitral valve, 4 such cases having been overlooked; 3 cases of mitral stenosis and a curious case of acute ulceration of the pulmonic valves were also not recognized. The relative frequency of the various lesions was as follows: aortic and mitral valves, 17 cases; mitral valves, 13 cases; mitral, aortic, and tricuspid, 2 cases; aortic alone, 5 cases; and pulmonic, 1 case. In 26 cases of valvular disease in which the history was known 9 had had acute articular rheumatism. In 32 cases the disease of the heart was dependent upon arteriosclerosis. More than half of these cases were over 50 years of age. In those below this age alcohol was a marked factor. In 14 of the cases there was a structural disease of the kidneys. Rheumatism was commonly absent. 16 of the cases suffered from fatty or acute degeneration of the muscular substance; 2 cases of fatty degeneration occurred in pernicious anemia, and 1 each in phosphorus-poisoning and carcinomatous cachexia; 60% of the cases of heart-disease were dependent upon arteriosclerosis.

Pott[2] discusses the **etiology of heart-disease in children,** and bases his views on 95 cases which occurred among 30,000 children. Rheumatism and acute infectious fevers form by far the most frequent causes. A masked form of rheumatism in which fever, nasopharyngeal catarrh, enlarged cervical glands and spleen, herpes on the lips, and pains in the limbs occur is a frequent antecedent to heart-disease; 1 case of congenital heart-disease occurred in a child whose mother had rheumatism during pregnancy. Congenital syphilis was the probable cause in 3 cases.

Allyn[3] considers the relation of **heart-disease and pregnancy.** Mitral disease, particularly stenosis, is more serious than aortic trouble, but there is a natural attempt at prevention in the frequency of sterility among subjects having mitral stenosis. Cardiac disease frequently leads to abortion. Mixed lesions are more serious than simple ones.

[1] Boston M. and S. Jour., May 21, 1896. [2] Fortschr. der Med., Nov., 1895.
[3] Univ. Med. Mag., Dec., 1895.

Von Weismayr[1] reports 6 cases from the service of Professor Schrötter in which tuberculosis and valvular disease of the heart occurred coincidently. In 3 of these cases the tubercular process was evidently slow or chronic in its course, and from this fact, as well as from the small number of cases found in a large clinical service, he concludes that the old principle of Rokitansky still holds good, that the congestion resulting from a cardiac lesion makes the lung resistant to tuberculosis. He cites the statistics of Frommold, who found 21 cases among 226 of valvular disease, and of von Kryger, who found 10 cases of valvular disease in 1100 autopsies on tuberculous patients. [The coincidence of cardiac disease and tuberculosis of the lungs has not been unusual in our experience.]

General Symptomatology.—Gerhardt[2] reports a case marked by decided bigeminal pulse in which sphygmographic and cardiographic studies showed that the anacrotic pulse was due to the contraction of the auricle. The case was one of aortic insufficiency with mitral stenosis and marked hypertrophy and dilatation of the auricles. In another case of aortic insufficiency a double pulse was palpable, but this was due to a decidedly elastic wave, probably dependent upon sudden tension of the vessel wall.

Stockton[3] describes as a symptom of cardiac insufficiency severe pain localized in the lumbar region, somewhat resembling the aching observed in those suffering from uric acid sand. It is promptly relieved by correcting the circulatory disturbances, but not by other methods of treatment. The majority of cases occur in men engaged in laborious outdoor work.

Fuller and Gibbs[4] reports the case of a girl of 15 in whom there was a cardiac murmur so loud that it could be heard at a distance of 12 feet from the patient fully dressed, or 3 feet outside a closed door, the patient being the same distance on the other side of the door with the chest exposed. The murmur varied in intensity at different times and seemed to be mitral. The only symptom was a slight breathlessness upon exertion. [We have ourselves seen a number of cases in which cardiac murmurs have been audible at a distance. The most striking was an instance of aortic aneurysm just above the valves, in which a loud to-and-fro murmur was plainly audible from 6 to 8 feet from the patient. A most interesting case occurred in the practice of Dr. Wm. Gerhard and Dr. Wm. Pepper the elder, in which a buzzing murmur afterward found to be due to a partially detached valve was audible throughout the patient's house.]

Phear[5] contributes an interesting paper upon **presystolic murmurs** heard at the apex **without mitral stenosis.** He first records 2 instances in which such a murmur existed and in which the aortic valves were entirely competent. In 1 of these the pericardium was adherent; in the other this structure was healthy. After considering the theories advanced in explanation of presystolic murmurs at the apex independent of mitral stenosis, he con-

[1] Wien. klin. Woch., Feb., 20–27, 1896.
[2] Zeit. f. klin. Med., Bd. xxix. p. 324.
[3] Brit. Med. Jour., 1895.
[4] Lancet, Apr. 4, 1896.
[5] Ibid., Sept. 21, 1895.

cludes that 2 factors are important: 1. Contraction of the chordæ tendineæ; 2. Dilatation of the left ventricle. Each of these factors is operative by stretching the mitral segments in a longitudinal direction, and thus bringing them more closely together than normal. In a certain sense this constitutes mitral stenosis, though the valves themselves are healthy. The author concludes his paper by brief abstracts of previously recorded cases, tabulating them in the following groups: 1. Cases with aortic regurgitation; 2. Cases with entire or partial adhesions of the pericardium; 3. Cases in which neither aortic regurgitation nor pericardial adhesions were discovered. The entire series includes 46 cases, in 17 of which the aortic valves were incompetent, and in 20 of which the pericardium was adherent. In 12 instances a presystolic or diastolic thrill was present. In 7 cases only the condition of the chordæ tendineæ was mentioned, being healthy in 3, thickened without shortening in 2, and shortened in the remaining 2.

Starling[1] states that he believes that **dropsy** is caused by the separate or combined action of 2 factors: 1. Increased exudation; 2. Diminished absorption by the lymph channels. The endothelial cells of the vessels, however, take no active part in the production of the exudate, their vital activities being confined to the maintenance of their integrity as a filtering membrane, with properties differing according to the part of the body in which they happen to be situated. The amount and composition of the lymph transuded in any part are determined solely by 2 factors: 1. The permeability of the vessel wall; 2. By the intracapillary blood-pressure. He has performed careful experiments to test whether exudation of lymph was in any way subject to the control of the nervous system, but he concludes that this is never the case, and when as a result of some nervous influence exudation takes place, it is simply due to a rise of capillary pressure, and is therefore only a secondary effect of the interference with the nerve. Even when there is increased transudation it is possible for the normal mechanism to hold this process in check by absorption for some time.

Davidson[2] has investigated very carefully the **cause of cardiac murmurs.** He reports a series of experiments which seem to show that the murmurs are due to the impingement of a stream of liquid obliquely upon a thin membrane. And he recites the physical law that when a membrane enclosing a liquid receives on its internal surface a stream that impinges against it at any angle whatever, it will be thrown into sonorous vibrations. These vibrations give rise to a sound when the stream impinges with rapidity and force, the pitch of the sound depending upon the relative thinness of the membrane (the thinner the membrane the higher the pitch), and the intensity upon the force with which the stream is emitted. A murmur is produced if the force is slight. Thus in aortic stenosis the left ventricle empties itself slowly, and the valves obstructing the outflow act as a membrane against which the stream impinges, giving rise to a murmur. In aortic insufficiency, on the other hand, recoil of the aortic wall produces a stream of liquid which regurgi-

[1] Lancet, May 9, 1896.

[2] Ibid., June 15, 1895.

tates into the ventricle, impinging against the aortic surface of the semilunar valves. If, however, the semilunar valves be completely removed, the murmurs will still be produced. This he has shown to be due to the impingement of the stream against the wall of the ventricle, thus proving that a muscular membrane enclosing a liquid can be thrown into sonorous vibration. He next undertakes to explain the cause of the first sound at the mitral orifice: this he believes to be due to the sudden striking of the blood against the ventricular surface of the mitral leaflets at the end of auricular contraction. The stream strikes the valves with great force, causing them to vibrate and giving rise to a sound. If, however, for any reason whatever, the rapidity of the stream be slowed, a murmur will be produced, and this accounts for the functional murmurs produced by a state of generally bad nutrition, as in chlorosis and the fevers, which are due to the weakened condition of the auricular muscle and the consequent slowing of its contraction. In mitral stenosis the murmur is rough in character, because the hypertrophied auricle contracts with considerable force and drives the column of liquid against the auricular surface of the mitral leaflets. In mitral regurgitation it might be supposed that the stream is sufficiently vigorous, providing there be no aortic stenosis to give rise to a sound; it must be remembered, however, that the period during which the stream acts upon the ventricular surface of the mitral leaflets occupies the whole period of ventricular contraction and is therefore considerably prolonged, and is thus able to give rise to a murmur. In conclusion, Davidson suggests a new nomenclature for the cardiac sounds, calling the first sound the auricular and the second the ventricular. He claims that arterial murmurs may be explained by the same acoustic principles. Thus if the stethoscope is pressed against an artery, its wall is forced inward, opposing a membrane to the current of blood. Geigel[1] has concluded that it is impossible that cardiac murmurs can be due to eddies, since even the lowest note requires at least 200 vibrations per second. He therefore thinks that the theory of lateral vibrations in the walls or valves due to the friction of the blood is the only rational one.

Mitral Stenosis.—Gouget[2] reports an interesting case of mitral stenosis and regurgitation occurring in a young woman of 34 who had suffered with rheumatism. She passed through 3 pregnancies without notable symptoms. Finally, signs of failure of compensation developed and she entered the hospital. At first there were discovered evidences of enlargement of the heart and of mitral stenosis, with a faint murmur at the apex that appeared systolic. The interesting feature, however, was the fact that the right radial pulse was scarcely palpable. The brachial, axillary, and subclavian pulses on the right side gave similar results. On the other hand, the left radial, brachial, and subclavian were easily palpable. The carotid pulse was perceptible on both sides, but more on the right than the left. Jugular pulsation was marked. Subsequently the conditions noted continued, but the signs of a double lesion at the mitral valve became very pronounced, and a systolic murmur developed over the second left interspace, being rather localized and having a soft charac-

[1] Virchow's Archiv, Bd. 140, Heft 2, S. 385. [2] Rev. méd., Sept. 10, 1895.

ter resembling the murmur of aortic insufficiency. The patient died, and at autopsy the heart was found enlarged, the mitral orifice was extremely contracted, and the pulmonary leaflets were incompetent (hydrostatic test). The author calls attention to 2 interesting features in the case: the occurrence of a murmur of pulmonary insufficiency, and the extreme feebleness and almost impalpable character of the right pulse. The pulmonary insufficiency is doubtless due, as he suggests, to over-distention of the pulmonary vessels and consequent enlargement of the orifice. The existence of such a murmur has been denied, but the case of Pawinski, as well as the present one, are undoubted instances. The disappearance and the reappearance of the murmur under treatment is interesting. The weakness of the right pulse is doubtless due, as was suggested by Popoff several years ago in a similar case, to pressure upon the arteries by the distended auricles or veins. In case of competence of the tricuspid valve the over-distention of the left auricle and pulmonary veins may compress the vessels of the left side, causing a weakness of the radial pulse on that side. When the tricuspid valve has become incompetent, over-distention of the venous trunks entering the right auricle may compress the innominate artery and its branches, and thus occasion weakness of the right pulse. This explanation is doubtless applicable in the present case.

Griffith[1] calls attention to the fact that nearly all text-books state that the murmur of mitral stenosis is practically limited to the region of the apex, though his own experience would show this view to be an incorrect one. Among 7 cases examined during the previous 3 months, he found 3 in which the murmur was audible in the back, 1 in which it extended 2½ in. beyond the left posterior axillary line, 4 in which it reached this line, and 2 in which it extended as far as the mid-axillary line. In each of the cases it was audible very high in the axilla. The case-histories are recorded, and diagrams of the chest, showing the distribution of the murmurs, indicate very clearly the degree of transmission of the sounds in these cases.

Heitler[2] refers to **pseudodiastolic murmurs** causing a mistaken diagnosis of mitral stenosis. He refers to a case in which a systolic mitral murmur was heard at the apex, followed after a short interval by a short diastolic murmur. Both murmurs were localized to the apex. The diastolic murmur, however, did not have the qualities of the murmur of mitral stenosis, and on careful examination it was noted that it mimicked the systolic murmur exactly, though it was much less distinct. Careful palpation of the carotid pulse showed that stronger beats alternated with weaker beats, and that the weaker murmur corresponded to the latter. Later the heart's action became more regular, the bigeminal character of the pulse ceased, and a systolic murmur alone was heard with each cardiac contraction and of constantly equal intensity.

Mitral Regurgitation.—Cantani reports a case of mitral regurgitation in which dilatation of the right heart commenced and marked insufficiency occurred. As death appeared imminent, it was resolved to perform **cardiocentesis,** and a puncture was made in the 6th interspace 1 in. from the

[1] Am. Jour. Med. Sci., Sept., 1895.

[2] Wien. med. Woch., Jan. 4, 1896.

sternum. A stream of bright scarlet blood spurted from the trocar, and in 5 days the man's cardiac symptoms had been completely relieved. He subsequently died of pulmonary phthisis, and at the autopsy it was found that the trocar had entered the left ventricle. Cantani expresses surprise that puncture of the left ventricle should have produced such efficient relief in this instance.

Heitler[1] records a case of mitral regurgitation in which the murmur was heard over the base of the heart.

Aortic Regurgitation.—Edwards[2] reports a case in which there was great dilatation of the heart and a soft blowing murmur, replacing the second sound at the aortic cartilage. At the autopsy the aortic and pulmonary valves were found competent by the hydrostatic test, and the valves were perfectly normal, and there were no thickenings, no adhesions, and no deformity. There was an uncomplicated hypertrophy of the left ventricle, and an incision showed numerous fibrous cicatrices between the muscle fibers, the larger part being found in the lower half near the apex. He concludes that there existed during life a relative aortic regurgitation, due, first, to dilatation of the aorta itself, and, secondly, to a dilatation of the left ventricle. Although the murmur of relative aortic insufficiency has been described as uncommonly loud, musical, and audible at some distance, in this case it was soft and blowing, exactly similar to the normal murmur of aortic regurgitation, so that the character of the bruit is of itself no guide in aiding the diagnosis.

Pulmonary Stenosis.—Hanot[3] records 3 cases of pulmonary stenosis, in all of which there was a strong tubercular family history; in 2 of the cases both the mother and father died of phthisis; 2 of these cases had shown signs of scrofula in childhood, but neither of them now present any respiratory disturbances. Hanot discusses the possibility of this form of stenosis being similar to the congenital narrowing of the aorta, such as occurs in chlorosis, and whether both are not manifestations of heteromorphous tubercular heredity. He believes it legitimate to suppose that in certain cases this narrowness of the pulmonary artery itself absorbed the whole or the greater part of the tubercular tendency, and therefore to a certain extent occasioned immunity against phthisis. [The frequent association of pulmonary stenosis and tuberculosis of the lungs is well established, but we question the justification of such a theory as that of Hanot just referred to.]

Adams[4] reports a case of sudden death in a boy of 14 who, aside from slight dyspnea on exertion, was apparently perfectly healthy. At the autopsy the right ventricle was found enormously hypertrophied and dilated, with adhesions between the pulmonary leaflets, leaving an opening scarcely $\frac{1}{4}$ in. in diameter.

Aufrecht[5] contributes an interesting article on **alcoholic myocarditis.** In the first stages the heart is found enlarged, and the sounds are clear or at

[1] Wien. med. Woch., Jan. 4, 1896. [2] Am. Jour. Med. Sci., Oct., 1895.
[3] Gaz. Hebdom. de Méd. et de Chir., Mar. 19, 1896.
[4] Boston M. and S. Jour., Jan. 30, 1896. [5] Deutsch. f. Arch. klin. Med., Bd. liv. H. 6.

most there is a low systolic bruit. The symptoms disappear after a time. In the later stages advanced cardiac failure with ascites, anasarca, enlargement of the liver, and not rarely albuminuria, occur. Dilatation and hypertrophy of the heart are invariably present. The author states that the condition referred to is the same as that described by Bollinger as idiopathic hypertrophy and dilatation of the heart. The latter author described it as rather acute, but Aufrecht holds that it extends from 3 to 5 years, and cites 3 cases which came under his observation. It is a disease of the better classes and is quite general in distribution. Alcohol in any form may bring it about, and men between 25 and 50 are more commonly affected. The first symptom is shortness of breath or pressure in the region of the heart. The heart is found enlarged, due to dilatation which precedes hypertrophy. This primary dilatation Aufrecht holds to be due to alcoholic weakening of the muscles. It is difficult to distinguish from chronic nephritis with its consequences, and from fatty heart.

Laache[1] in an elaborate article on the **nonvalvular affections of the heart** refers particularly to the so-called idiopathic hypertrophy and the degenerations of the cardiac muscle. He points out that the morbid changes in the myocardium may be of various kinds, and states that according to his view the "idiopathic hypertrophy" of the Germans is not a special disease, but rather a group comprising different affections. In the discussion of the etiology particular stress is laid upon alcohol. Over-exercise of the heart is an important factor, but he warns against the assumption that this is the all important cause, in view of the fact that many cases show other causes at the same time. As far as his own experiences in Norway are concerned, he refers to the exercise of the "ski" as a frequent cause of disturbances which are explainable as a result of cardiac weakness, and refers to the expression "*at sprange sig*" as a popular indication of the role played by distention of the heart in these accidents. In certain cases he admits it is impossible to find causes, and in these it is permissible to apply the term idiopathic. The symptomatology and the treatment are elaborately discussed, and extensive references are made throughout to the literature.

Rieder[2] discusses much the same subject, and in particular hypertrophy of the heart due to overexercise. He reports 3 cases which were carefully observed for a long time. The first affected a student aged 24; the other 2 cases occurred in laboring men, aged respectively 27 and 19. In the first case over-exertion was acute and occurred in mountain-climbing; in the second and third cases the strain was more gradual and occurred in the ordinary daily occupation of the patients. While it is certain that a perfectly healthy heart may suffer from over-exertion, there was reason, in the 3 cases reported, to believe that preexisting disease aided in the subsequent dilatation and hypertrophy. In the first case there was a history of excessive consumption of beer (10 to 12 liters a day). In each of the cases the symptoms of disturbed cardiac action were distinct and the signs of hypertrophy and dilatation evident. The first recovered, and the dilatation (possibly hypertrophy also) subsided, and the

[1] Rev. méd., Sept. 10, 1895.

[2] Deutsch. Arch. f. klin. Med., Mar. 13, 1896.

patient subsequently gave no evidence on physical examination of a preexisting disease. In regard to treatment the beneficial action of calomel was noted in cases 1 and 2, and of digitalis in cases 2 and 3. The description of the cases is followed by a systematic discussion of the entire subject of idiopathic diseases of the heart.

Fisher[1] finds among the records of the hospital during 10 years 22 cases of hypertrophy of the heart without gross organic lesion; 8 of these cases were alcoholics, 3 had suffered from over-exertion, and 3 had atheroma of the peripheral arteries. The remaining 8 cases were of doubtful origin. The clinical features of these cases differed little from those of organic disease of the heart. Signs of failing compensation occurred frequently, and systolic murmurs could be heard at the apex or on the right side. Anginoid attacks sometimes occurred in the earlier stages. It is striking that cirrhosis of the liver scarcely ever occurred in the alcoholics.

Edwards[2] reports a case of **chronic fibrous myocarditis** in which the signs of aortic regurgitation were pronounced, though the autopsy showed that the valves were entirely normal. The patient, a negro laborer of 54, had been an excessive drinker, and had suffered with rheumatism for 9 months. The cardiac symptoms began 4 years before admission. When he came under the author's notice the heart was greatly enlarged; there was a diastolic murmur and pulsation of the vessels, Traube's sound, and other evidences of pure aortic regurgitation. The patient grew worse and died. At the autopsy marked atheroma of the coronary arteries and advanced myocarditis were discovered, but the valves were normal and were competent to the hydrostatic test. The author concludes that this was an instance of functional or relative insufficiency, and reviews the literature of this subject. He has been unable to find more than 25 cases of this character, and some of these are reported twice. The review of the literature leads him to conclude that, despite the view of eminent authorities, relative aortic insufficiency does occur, either from dilatation of the aorta in consequence of atheroma, senile involution, aneurysm, acute aortitis, or from dilatation of the left ventricle resulting from over-exertion, arteriosclerosis, aortic disease, synechia cordis, increase of arterial tension, parietal endocarditis, nephritis, fibrous myocarditis, or idiopathic dilatation. [The author states that "American authors do not mention its existence." This statement, however, is not entirely accurate. We have ourselves observed several instances of relative aortic insufficiency due to aneurysm and arteriosclerosis, and have recently met with a striking case of the same condition resulting from dilatation of the left ventricle in a case of pernicious anemia. Moreover, one of the editors has noted the occurrence of this condition in a systematic discussion of disease of the heart and vessels published several years since.[3]]

Radasewsky[4] believes that the cardiac arhythmia of chronic myocarditis

[1] Guy's Hosp. Rep., Lond., Perry and Jacobson, 1895. [2] Am. Jour. Med. Sci., Oct., 1895.
[3] Am. Text-Book of the Theory and Practice of Medicine, vol. ii. pp. 291 and 418.
[4] Zeit. f. klin. Med., Bd. xxii. p. 381.

is really due to degeneration of the walls of the auricles. He examined the hearts of 6 cases, in 2 of which the cardiac action had been regular, and in these the walls of the auricles were intact; whereas in the other 4 in which arrhythmia had existed they were considerably diseased.

Treatment of Cardiac Diseases.—[Considerable attention has been given in the last few years to the method of treatment pursued at Nauheim under Schott. Undoubtedly graduated gymnastic exercise and warm bathing are useful measures of treatment in suitable cases, but certain very proper criticisms may be offered when a routine plan is adopted for all cases and adequate discrimination is neglected. Besides this, it may be remarked that little reliance can be placed in the statistics published to show the general usefulness of the method.]

Saundby[1] describes the **Nauheim or Schott treatment** of heart-disease, consisting of warm saline baths and exercise. The effect of both is to increase the force and the rate of the pulse and to contract the area of cardiac dulness. Sphygmographic tracings showed that the rate of the pulse and its force are increased during the movements and immediately afterward. Saundby has himself tried the treatment in several cases. In 1 case of exophthalmic goiter the result was doubtful, but the patient claimed to feel improvement; 2 cases of chronic mitral disease were improved, 1 was made worse, and 1 is still under treatment. Saundby, in opposition to Schott, believes that the primary effect of baths and exercise is on the peripheral circulation, but that their action is to raise the blood-pressure, the heart becoming slower in accordance with Marie's law. The benefit to the system is due to the careful and easily regulated method by which the extra work is imposed upon the muscular wall. He concludes by the suggestion that there is a large group of cases suitable for application of this treatment in private practice, among others, cases of weakened heart occurring after acute disease, such as rheumatism, influenza, etc.

Leith[2] has studied very carefully the physiologic effects of bathing as given according to the Schott system at Nauheim, his results agreeing with those of other investigators. He found that the **resisted gymnastics** seemed to have an appreciable influence upon the area of cardiac dulness; but trivial actions—that is, a few minutes of gentle exercise or even a change of posture —had also an appreciable influence. Thorne[3] in advocating the Schott method of treatment for cardiac diseases calls attention to the changes discoverable in the size of the heart and in circulation during this treatment. There is immediate evidence of dilatation of the peripheral blood-vessels and diminution in the size of the heart. This results from the direct effect of the warm baths upon the distribution of the blood. In determining the size of the heart he uses the method of auscultatory percussion. Broadbent[4] in his criticism of Dr. Thorne's contribution upon the Schott treatment of cardiac diseases makes the following timely remarks upon this method: "The Schott

[1] Brit. Med. Jour., Nov. 2, 1895.
[2] Edinb. Med. Jour., Mar., 1896.
[3] Brit. Med. Jour., Mar. 14, 1896.
[4] Ibid., Mar. 28, 1896.

method has undoubtedly potentialities of usefulness in certain forms of heart-disease, and it is a matter of great interest and importance to ascertain with some degree of certainty and precision in what class of cases it is of most service. No advance can be made in this direction while it is employed indiscriminately in all forms and stages of heart-disease, including cases in which perfect compensation has been obtained and cases in which no real heart-affection exists, nor while statements are made which seem to imply that it is equally efficacious under all circumstances. It must be borne in mind, too, that any treatment which is powerful for good can also when misapplied do harm; grave risk, for instance, is incurred when the Schott methods are practised in cases of aneurysm. Herschell[1] also questions the value of the Nauheim treatment of cardiac disease, and records 4 cases in which he has employed warm baths without beneficial effect and perhaps with positive detriment. As far as the reported benefits are concerned he believes that many cases supposed to have been benefited or cured are instances in which the patient had suspected cardiac disease, but in which it had not existed. Other cases he believes are instances in which compensation was not disturbed or in which gross errors of diet and of daily hygiene had existed which were temporarily corrected. Finally, he refers to the case of a man who had undertaken the treatment at the advice of friends, with the result that his compensation, previously good, was broken and death ensued.

Ennesbuske[2] describes the **various forms of gymnastics** that have been employed in the treatment of cardiac conditions. He groups them under 3 heads: The manual gymnastic method of Ling; the medico-mechanic method of Zander; and the mountain-climbing method of Oertel. The conditions treated are valvular diseases, fatty heart, weak heart, and uncomplicated hypertrophy. The indications are to increase the force of the systolic stroke and to relieve venous hyperemia and hydropic exudations. The treatment should usually consist at first of manipulations and passive movements; later very mild active movements may be permitted. He reports several cases of mitral incompetency with symptoms of mild degree in which he was enabled by gymnastic movements to reduce the heart-rate on an average of 10 to 15 beats per minute after an hour's gymnastics, with more or less permanent improvement in the general condition.

Zabludowski[3] advocates massage—that is, the passive movements—in cases of heart-disease. He believes that the movements should not be carried out in too delicate a manner, but practised energetically for about 10 or 15 minutes every day, preferably in the morning. He reports 3 cases, 1 of nervous palpitation, 1 of cardiac insufficiency, and 1 of commencing aortic insufficiency, all of which were greatly improved by this treatment. He has also used it with good effect in Grave's disease.

Högerstedt[4] contributes a monograph upon the effect of circulatory dis-

[1] Lancet, Feb. 15, 1896.
[2] Boston M. and S. Jour., June 18, 1896.
[3] Berl. klin. Woch., May 26, 1896.
[4] Ueber chronische cirkulationstörungen, etc., St. Petersburg, Wienecke, 1895.

turbances upon the blood-pressure and the influence of warm baths. He finds quite a constant increase in the blood-pressure of the arteries, the general circulation in attacks of palpitation, and other disturbances of the cardiac action. No relation can be drawn between the blood-pressure and the presence or absence or the amount of peripheral venous engorgement. Warm baths (30° R.) cause a lowering of the blood-pressure temporarily, and exercise a happy effect in the gradual restoration of normal conditions of the circulation.

McColl[1] relates his personal experience regarding the **effect of altitude** upon cardiac disease. He has suffered for 25 years with attacks of acute rheumatism (9 in all), and has diseased mitral valves with fair compensation. On several occasions during visits to places having an elevation of 5000 to 10,000 feet he has experienced great comfort, the cardiac fatigue, depression, and the sense of emptiness at the top of his head disappearing almost at once.

Medicinal Treatment.—Balfour[2] in a paper on the digitalis-group in the treatment of heart-disease, states that **strophanthus** is a valuable member of this group. It has no pretensions to rival digitalis, being so much less certain in action, and so devoid of tonic properties that he is not tempted to displace digitalis in its favor. Strophanthin has two advantages over digitalin: it is readily soluble in water, and is rapidly absorbed. Regarding the applicability of digitalis, he says it may be beneficially employed in all cases, whatever may be the cause or nature of the concomitant lesions. Even when compensation appears well established no harm can result from giving tonic doses of the remedy. He does not agree that its action is generally bad in aortic regurgitation, and he has never seen damage accrue from its use in feeble and dilated hearts, so commonly regarded as fatty. The most suitable preparations are the fresh leaves, the infusion ranks next, and the tincture last.

Vatin[3] has investigated the action of **digitoxin** in cardiac diseases. He finds that it produces slowing and regularity of the pulse, improvement in respiration, and diuresis. Occasionally there was nausea and vomiting after its administration. It is indicated particularly in cardiac insufficiency; it is contraindicated in venous stasis with secondary changes and in gastric disturbances.

Morrison[4] in considering the **treatment of aortic valvular diseases** maintains that the circulation is not alone dependent upon the propulsion caused by the contractions of the ventricle, but ascribes it partly to aspiration of the left ventricle itself and to that exercised by the chest-cavity during inspiration. He holds that in aortic regurgitation digitalis is comparatively useless, as the indications call for remedies which will quicken circulation, such as belladonna, strychnin, and nitrites. Digitalis and its congeners are specially useful in mitral regurgitation, in which maximum aspiration is required.

Askanazy[5] has carefully studied the clinical action of **diuretin,** and concludes that it is a reliable diuretic in disease of the heart and vessels, but less

[1] The Physician and Surgeon, Aug., 1895.
[2] Brit. Med. Jour., Dec. 14, 1895.
[3] Gaz. Hebdom. de Méd. et de Chir., Apr. 5, 1896.
[4] Brit. Med. Jour., Mar. 14, 1896.
[5] Deutsch. Arch. f. klin. Med., Dec. 13, 1896.

valuable in chronic nephritis. It acts promptly and very uniformly against attacks of cardiac asthma, angina pectoris, or conditions of chronic cardiac dyspnea such as occur in aortic insufficiency and chronic nephritis. If as much as 5 or 7 grams a day are given, severe collapse occasionally occurs, and he therefore recommends a maximal dose of not more than 4 grams. [We have found the drug most useful in some cases, but it occasionally produces severe headaches and gastric disturbances.]

Huchard[1] considers **theobromin** one of the best and most uniformly reliable drugs for the treatment of anasarca and edema accompanying renal and cardiac diseases, and states that it acts directly upon the renal epithelium.

Murray[2] speaks of the extreme value of **mercury** in certain forms of heart-disease, and reports the case of a Scotchman who suffered from extreme cardiac insufficiency, and in whom none of the ordinary stimulants were of any benefit; he was immediately improved, however, by large doses of blue pill, and continued using the drug for ten years, living for that time in comparative comfort and working hard. At the postmortem the heart was found to be enormously increased in size, the tricuspid orifice admitted 8 fingers, and there was extreme constriction of the mitral orifice.

DISEASES OF THE MYOCARDIUM.

Pässler and Romberg[3] discuss the causes of **disturbances of the circulation in infectious fevers.** Romberg with Bruhns and Pässler previously showed that in cases of pneumococcus and pyocyaneus infections central paralysis of the vasomotor system, and not cardiac weakness, caused disturbance of the circulation. The present investigations were made with diphtheria, and a similar result was obtained. They found the heart-action slowed and somewhat irregular, and the fall of blood-pressure due to the paralysis of the vasomotor center in the medulla. Romberg[4] believes that it is possible to discriminate between weakness of the cardiac muscle and vasomotor paresis by the fact that in the latter case abdominal massage causes increase in the blood-pressure.

Chronic Myocarditis.—[The importance of chronic diseases of the myocardium has never been properly appreciated, despite the important contributions of older writers. At the present time there is, fortunately, a tendency to investigate the muscular defects of the heart, and a more general knowledge of their importance as independent affections and as concomitant conditions in chronic valvular disease is observable. We have ourselves studied with much interest cases of myocardiac degeneration leading to pronounced failure of circulation, and have been particularly impressed by the abundance of such cases in the wards of the Philadelphia Hospital. The character of many of the patients of that institution is a sufficient indication of the probable causes: exposure, hard labor, alcoholism, and syphilis.]

[3] Centralbl. f. innere Med., Apr. 25, 1896; Berl. klin. Woch., Apr. 20 and 27, 1896.
[4] Centralbl. f. innere Med., 1895, No. 40.

Cardiac Neuroses.—Kisch[1] in a paper upon the cardiac disturbances that are likely to occur at the time of the establishment of the menstrual functions concludes that **nervous palpitations** and **paroxysmal tachycardia** are met with in a considerable number of cases, that the cardiac disturbances of chlorotic girls are dependent upon the establishment of menstruation, and that hypertrophy of the heart occurs in consequence of the circulatory disturbances incident to this time of life, as well as in consequence of the rapid growth and improper clothing of this period.

Sharpless[2] reports a case of miliary tuberculosis remarkable for the extraordinary **arrhythmia** of the heart. At various times the pulse in the course of a few beats would drop from the rate of over 100 to one less than 70. No causes could be discovered to account for this peculiar action.

English[3] reports a very extraordinary condition of the heart characterized by arrhythmia, dyspnea, palpitation, sighing, respiration, etc., which he believes was due to indulgence in **tomatoes.**

Morrison[4] reports 37 cases of **bradycardia.** Of these, 1 was under 20 years of age; 2 between 20 and 30; 2 between 30 and 40; 7 between 40 and 50; 6 between 50 and 60; 10 between 60 and 70; 7 between 70 and 80; and 1 between 80 and 90; 31 of the patients were males, a proportion which agrees with results obtained by Grob, who found 131 cases in males and 9 in females. The common cause of the cases occurring under 40 years seems to have been excessive muscular strain. Syphilis is also recorded in 2 cases. He believes that, as recovery sometimes occurs, a heart healthy as to its muscles may become acutely dilated. Another local cause is the actual stenosis at the aortic orifice due to changes of the aortic cusps (or a virtual stenosis due to dilatation of the left ventricle). Another condition having the effect of slowing the heart's action is the increase of the resistance of the vascular system which comes with age. The impediment to the thoracic or abdominal respiratory action, such as occurs in obesity, may be a subsidiary factor in the case. Pregnancy and fasting also cause slowing of the pulse-rate. Unusual retardation is very rarely physiologic, and must be regarded as syncopal in tendency, whether it be transient or persistent. Cases may also occur in which the nervous mechanism of the heart is more affected than the heart-muscle, and in these Morrison thinks that the fault probably lies in the accelerant as well as in the inhibitory system of the heart, and that the elucidation of this condition requires investigation of the accelerant motor tracks from their origin to their termination.

Riesman[5] uses the term **paulocardia** to designate the subjective sensation of intermission or stopping of the heart that is sometimes observed in cases of gastric neurasthenia.

Schott[6] describes various **gouty affections of the heart.** In 1 case he observed extreme bradycardia; in 2 other patients, suffering from chronic gout,

[1] Berl. klin. Woch., Sept. 30, 1895.
[2] Med. News, Dec. 14, 1895.
[3] Jour. Am. Med. Assoc., June 27, 1896.
[4] Lancet, Nov. 25, 1895.
[5] Phila. Polyclinic, vol. iv. No. 36, p. 363.
[6] Berl. klin. Woch., May 25, 1896.

he observed the gradual development of aortic stenosis. Usually the symptoms are those of cardiac neurosis, and frequently there is dilatation of the right ventricle. In 1 case repeated severe attacks of angina pectoris were permanently cured by treatment directed only to the gouty conditions. The treatment consisted in careful diet and hygiene and the ordinary methods of treating gout and such cardiac complications as may have been produced. Regarding hydrotherapy, he warns energetically against the danger of the production of a gouty crisis, as this usually produces permanent injury to the heart.

Wadleigh[1] advocates the use of **strophanthus** in angina pectoris, and has used it in several cases with very good effect.

EXOPHTHALMIC GOITER.

Etiology.—Brissaud[2] contributes an elaborate study of the theories regarding the **nature of exophthalmic goiter,** and concludes that it is impossible at the present time to formulate a satisfactory explanation. Grave's disease is a group of symptoms rather than an independent disease. Regarding the pathologic changes in the thyroid little satisfactory knowledge exists, and the author points out that in 25 cases of various chronic diseases he has found changes in this gland. It is difficult to accept the view that the disease is caused by an affection of the medulla oblongata, since this does not explain the enlargement of the glands, unless Fillehne's and Derdufie's observations on rabbits, showing the development of exophthalmos, enlargement of the thyroid, and tachycardia after removal of the restiform bodies, are to be considered. Undoubtedly disturbance of the function of the glands plays some part, but the nature of this remains in question. Regarding the treatment, he holds that injection or use of thyroid extracts is still an experimental stage.

Martius[3] in a discussion of the same subject reviews the theories of Möbius, who holds that the disease is a form of toxemia due to morbid action of the thyroid gland, and of Buschan, who holds that it is due to disturbed innervation. He points out that the theory which locates the disease in the medulla oblongata is not supported by pathologic evidence, while that which hypothecates disease of the sympathetic nerves lacks support from the fact that it fails to explain certain of the manifestations. His own view is that there is a disease of the central nervous system, and he points out that it has a resemblance to a chronic intoxication. Whether this is due to poisons produced by the thyroid gland, or by such as are allowed to circulate from inhibition of the destructive action normally exercised by the thyroid gland, remains unsettled.

Putnam[4] discusses very thoroughly exophthalmic goiter. He objects to the theory that the disease resides in the medulla oblongata, because the lesions found are neither uniform nor constant, and therefore are probably secondary not primary. He thinks also that the theory of thyroidal secretion is still extremely vague and lacks a sound basis. Of 2 cases in which Putnam recommended extirpation, 1 died on the eighth day after the operation with-

[1] Med. News, Mar. 14, 1896.
[2] Mercredi méd., No. 34, 1895.
[3] Berl. klin., May, 1896.
[4] Boston M. and S. Jour., Aug., 1895.

out apparent cause, and the other was seriously prostrated for a long time, but gradually improved. It was suggested that her serious prostration might be due to the absorption of some part of the large quantity of thyroid secretion that escaped from the wound. He believes that probably the best treatment is the local use of electricity applied by prolonged faradic currents, so as to literally squeeze out the contents of the glands. Parenchymatous goiters sometimes disappear with great rapidity as a result of feeding with thyroid extracts. Regarding the theory of hypersecretion of the gland, he objects that some of the symptoms of exophthalmic goiter may appear when the gland shows no enlargement whatever, and it is not proved that a normal thyroid may have a hypersecretion. Another objection is that thyroid preparations do not always aggravate, but sometimes relieve, the symptoms. He also objects to the theory that the thyroid secretion is vitiated. The removal of a part of a morbid goiter relieves the symptoms, but it should not alter the nature of the secretion. He finally concludes that the symptom group of this disease really indicates a mode of dissolution of the nervous system, and he regards it as a degenerative neurosis making a line of cleavage at some point at which the nervous functions were exposed to the strain. In the discussion following this paper Dr. Shattuck declared that in his experience the administration of thyroid had not given encouraging results. Kinnicutt[1] in discussing the possibility of the thyroid origin of Graves' disease refers to 4 cases collected from the literature in which, after attacks of classical Graves' disease, myxedema developed and was cured by the thyroid treatment. [It must be admitted, after a careful review of existing knowledge, that the solution of the question of the etiology of the disease under consideration is still quite distant. The theories ascribing it to primary thyroid disease are attractive, and seem to be supported by certain facts, but other evidence is of a decidedly contrary kind.]

Symptoms and Diagnosis.—Abram[2] describes 5 cases, in 2 of which autopsies were performed. In 1 of the cases the symptom of Joffroy was discovered—viz. the absence of facial contraction when the patient suddenly turned her eyes upward. Tremor was a constant and early symptom. Exophthalmos generally occurred late, and was ascribed to distention of the vessels behind the globe. In one of the cases it disappeared suddenly during an attack of diarrhea. In the fatal cases he found no increase of the intraorbital fat. The thyroid glands in the second fatal case were enlarged and the alveoli small and filled with cells. Colloid material was absent. In 1 of the cases of rather acute character masses of leukocytes were found at the point of entrance of the large bloodvessels. There was no excess of vascularization. The author regards the disease as a result of excessive secretion of the gland.

Fridenberg[3] reports a case of exophthalmic goiter, in which the ocular symptoms and the thyroid enlargement were unilateral, and he refers to 13 other cases similar in character recorded in literature. Of these, 3 presented left-sided exophthalmos like his own, but 1 of these had enlargement of the

[1] Med. Rec., Apr. 18, 1896.

[2] Lancet, Nov. 16, 1895.

[3] Med. Rec., July, 1895.

thyroid gland of the opposite side. His own case was a woman of 24, married 4 years previously, who had aborted a year later, but had not been subsequently pregnant. Domestic disturbances had arisen, especially during the last 6 months, and within a few weeks of her first appearance she presented nervous excitability, palpitation, fatigue after slight exertion, and dyspnea. The left eye presented exophthalmos with Graefe's sign; the right eye was normal. The left side of the face was slightly more reddened than the right, and the right half of the thyroid and the isthmus were enlarged.

Maybaum[1] holds that the diagnosis of **abortive exophthalmic goiter** (*struma exophthalmique fruste*) should be made only when two of the cardinal symptoms are present, and when the third is absent for a long time. If the latter were not the case, the diagnosis would rather be that of Graves' disease passing from a milder to a severer stage. The author reports 2 cases, in the first of which exophthalmos and tachycardia with tremor and other nervous symptoms, but without thyroid enlargement, occurred, and in the second tachycardia and enlargement of the thyroid gland and nervous symptoms, but no exophthalmos. Donellan[2] reports a case without exophthalmos.

Regarding the **prognosis** of Graves' disease, Pribram[3] states that in a large proportion of cases, hospital treatment, with rest and care, is often followed by improvement and sometimes by recovery. He has seen recovery in cases in which even dropsy or other serious complications were present.

Treatment.—Stabel[4] reports 10 cases of Basedow's disease in which **thyroid glands** or tablets of **thyroidin** were administered. In 3 cases the gland itself was given, but in each the results were disturbing. In the other 7 cases the thyroidin tablets were used without the least beneficial effect even in the cases treated early, and in all of them excessive rapidity of the pulse and nervous disturbance were produced. He therefore concludes that the remedy is contraindicated in this disease. Silex[5] reported to the Berlin Medical Society a case of exophthalmic goiter in which thyroid extract proved efficient. The patient was a woman of 40, whose illness began Feb., 1895. She had been treated with arsenic without success, and was in a most critical condition when thyroid tablets were given her by a friend. She took large doses of these, and improvement was at once remarkable, and in a short time she was restored to a normal condition. Ewald, in discussing the above, remarked that though the case which he reported a year ago was not benefited by the thyroid extract, such cases as Silex's had been observed, but must be looked upon as exceptional. [We are disposed to coincide with Ewald. Certain cases have undoubtedly been favorably influenced by thyroid treatment, though our own experience has been unfavorable.] V. Jaksch[6] states that he has found thyroid treatment of no value in 6 cases of Grave's disease, though it has caused no unpleasant symptoms.

Surgical Pathology and Therapeutics.

BY

JOHN COLLINS WARREN, M. D., LL. D.,

Professor of Surgery, Medical Department Harvard University; Surgeon to the Massachusetts General Hospital, etc.

A handsome octavo volume of 832 pages, with 136 relief and lithographic illustrations, 33 of which are printed in colors, and all of which were drawn by William J. Kaula from original specimens.

Prices: Cloth, $6.00 net; Half-Morocco, $7.00 net.

"The volume is for the bedside, the amphitheatre, and the ward. It deals with things not as we see them through the microscope alone, but as the practitioner sees their effect in his patients; not only as they appear in and affect culture-media, but also as they influence the human body; and, following up the demonstrations of the nature of diseases, the author points out their logical treatment."—*New York Medical Journal.*

MEDICAL DIAGNOSIS.

BY

DR. OSWALD VIERORDT,

Professor of Medicine at the University of Heidelberg.

Translated, with additions, from the Second Enlarged German Edition, with the Author's permission, by Francis H. Stuart, A. M., M. D. Third and Revised Edition.
In one handsome royal-octavo volume of 700 pages, with 178 fine wood-cuts in text, many of which are in colors.

Prices: Cloth, $4.00 net; Sheep or Half-Morocco, $5.00 net.

In this work, as in no other hitherto published, are given full and accurate explanations of the phenomena observed at the bedside. It is distinctly a clinical work by a master teacher, characterized by thoroughness, fulness, and accuracy. It is a mine of information upon the points that are so often passed over without explanation. Especial attention has been given to the germ-theory as a factor in the origin of disease.

For Sale by all Booksellers, or sent post-paid on receipt of price.

ANOMALIES

AND

CURIOSITIES OF MEDICINE.

BY

GEORGE M. GOULD, M. D., AND WALTER L. PYLE, M. D.

Several years of exhaustive research have been spent by the authors in the great medical libraries of the United States and Europe in collecting the material for this work. **Medical literature of all ages and all languages** has been carefully searched, as a glance at the Bibliographic Index will show. The facts, which will be of **extreme value to the author and lecturer,** have been arranged and annotated, and full reference footnotes given, indicating whence they have been obtained.

In view of the persistent and dominant interest in the anomalous and curious, a **thorough and systematic collection** of this kind (the first of which the authors have knowledge) must have its own peculiar sphere of usefulness.

As a complete and authoritative **Book of Reference** it will be of value not only to members of the medical profession, but to all persons interested in general scientific, sociologic, and medico-legal topics; in fact, the general interest of the subject and the dearth of any complete work upon it make this volume **one of the most important literary innovations of the day.**

An especially valuable feature of the book consists of the **Indexing.** Besides a complete and comprehensive **General Index,** containing numerous cross-references to the subjects discussed, and the names of the authors of the more important reports, there is a convenient **Bibliographic Index** and a **Table of Contents.**

The plan has been adopted of printing the **topical headings in bold-face type,** the reader being thereby enabled to tell at a glance the subject-matter of any particular paragraph or page.

Illustrations have been freely employed throughout the work, there being 165 relief cuts and 130 half-tones in the text, and 12 colored and half-tone full-page plates—a total of over 320 separate figures.

Handsome Imperial Octavo Volume of 968 Pages.
PRICES: Cloth, $6.00 net; Half Morocco, $7.00 net.

W. B. SAUNDERS, Publisher,
925 Walnut St., Philadelphia.

Scholz[1] has investigated the effect of thyroid extract upon metabolism in a patient suffering with exophthalmic goiter as contrasted with the effect in a healthy person. He found the excretion of nitrogen slightly less than the ingestion in both cases, before the treatment. After the administration the nitrogen elimination increased somewhat, but not greatly. The most marked disturbance detected concerned phosphorus-elimination. There was but a slight amount of phosphorus in the excreta before the administration. After the administration it increased remarkably, especially the intestinal elimination, which became 10 times as great as before the treatment.

Eder[2] reports a case of exophthalmic goiter that was treated with thyroid extract, potassium bromid, hypodermic injection of nuclein prepared from spleen, and extract of spleen, without benefit. She was then treated with an **aqueoglycerin extract of thymus gland,** and showed slight improvement (purely subjective). Six months later, still continuing the treatment, the pulse had dropped from 104 to 92 (single observation) and the patient "felt better."

Starr[3] has found **glycero-phosphate of sodium** useful, and reports an instance in which there was rapid improvement after all other forms of treatment had been employed without effect for 1½ years. The drug is administered in doses of 20 gr. 3 or 4 times daily. The remedy was introduced by Trachewsky, and has been employed successfully by Chibret.

Rhenier[4] believes that a larger number of successes are to be attributed to the **electric treatment** of exophthalmic goiter than to any other method. He prefers galvanism, and states that the diminished frequency of the heart-beats is marked after the application. Bartholow[5] reports 2 cases of exophthalmic goiter, 1 completely cured and the 2d much improved by persistent galvanism and the internal use of duboisin, picrotoxin, iron, manganese, and in the 2d case also thyroid extract.

Claude Wilson[6] reports a case which had been treated unsuccessfully by the usual remedies. Thyroid extract and thymus gland had not been tried. He finally decided to use the **Schott method** of treatment of cardiac disease, and gave saline baths at 90° F. with marked benefit. [In connection with cases like the above it is well to remember that certain cases of cardiac disease with marked failure of compensation present symptoms very like those of primary exophthalmic goiter.]

Starr[7] has collected **190 cases** of exophthalmic goiter in which some form of **operation** was done. Of these, 74 are reported as completely cured, many of them having been watched 2 to 4 years before the result was published. Exophthalmos sometimes persisted for a year after operation; 45 of the cases were improved and 3 were not benefited; 23 cases died immediately after operation, and, as hemorrhage was not the cause and careful aseptic precautions

[1] Centralbl. f. innere Med., Oct. 26, 1895. [2] Boston M. and S. Jour., Jan. 23, 1896.

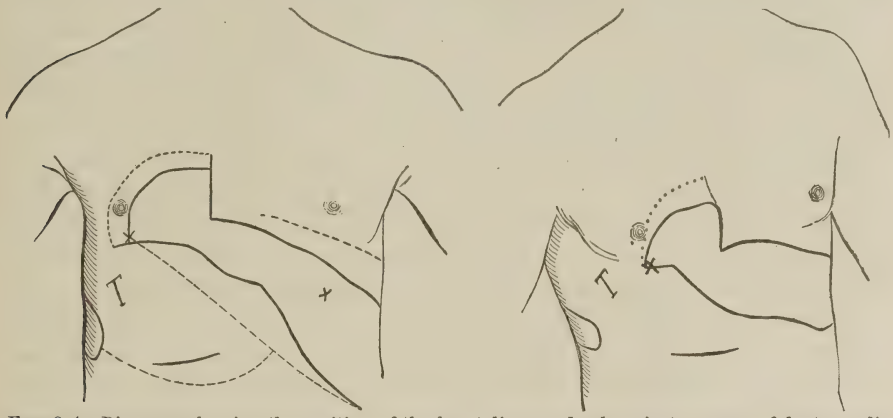
[5] Med. News, Nov. 16, 1895. [6] Practitioner, Sept., 1895. [7] Loc. cit.

were taken, he holds that the cause of death is a sudden poisoning of the system by excessive absorption of thyroid juice. This may be due to the manipulation of the thyroid gland or to the increased absorption by torn vessels or to the stimulation by the ether. He approves Kocher's suggestion that local anesthesia by cocain should be used instead of ether. The symptoms preceding the fatal result are sudden hyperpyrexia with rapid pulse, nervous distress, sweating, cardiac failure, and collapse. Kinnicutt[1] has collected altogether 187 cases in which surgical operation was undertaken. Of these, 13 died as the result of the operation, 60 recovered, 47 improved, 11 were unimproved, and in 25 the result is unknown; 31 cases reported by Kocher have either improved or been cured. Abram[2] refers to 138 cases in which operation was undertaken. Of these, 114 were improved, 17 cured, and 4 died.



Congenital Heart Disease.—Jacobi[3] reports the case of a man who died at 29 with **patent ventricular septum.** In 1891 he had an attack of great dyspnea, palpitation, and lividity. There was a loud cardiac murmur. Four years later a second severe attack occurred, and at this time it was noted that the superficial veins were not distended, though there was marked cyanosis. The impulse of the heart was strong, but the size of the organ little if at all increased. There was a loud systolic murmur about the ensiform cartilage. Pneumonia developed, and subsequently facial palsy. The patient died, and postmortem the heart was found slightly enlarged. The pulmonary artery was normal, but had no conus. The aorta was small, and the innominate, the left carotid, and the subclavian arteries were all small and branched off before the arch was formed. The ventricular septum was defective in its upper part. The foramen ovale was closed. No ductus Botalli could be found.

Boisdeau[4] reports an interesting case of congenital heart-disease. The child at birth breathed badly and was completely cyanosed. Either side of the neck was occupied by great swellings which proved to be enlarged veins, and it is of interest to note that the head was smaller than normal, the biparietal diameter being 7 cm., the occipitomental 10 cm. The child died some hours after birth, and the autopsy showed cicatricial retraction of the tricuspid leaflets, with enlargement of the orifice and great dilatation of the auricle.

Gerrard[5] reports a case of **dextrocardia.** The apex-beat was situated on the right side $4\frac{1}{2}$ inches external to the ensiform cartilage, and no impulse was to be found in the normal position of the apex. The superficial cardiac dulness extended from the third right interspace to the liver. A harsh fremissement was felt at the apex. A double murmur was heard at the mitral and in the normal aortic region. A murmur was also heard at the pulmonic cartilage. The patient had had rheumatism, but so slightly that Gerrard believes the cardiac lesions were probably congenital. Another instance of transposition of the heart was reported by Haines[6]. Posselt[7] reports 2 cases of transposition in healthy adults. (See Figs. 3, 4.)

Rupture of the Heart.—Kouskoff[1] records a case of rupture of the heart, and refers to the rarity of the condition. He observed it but 3 times in 8000 autopsies. In the present case the patient, a professor in the University of Kieff, had been suffering with influenza for 10 days. The sputum and stools were bloody and there was a slight cough. The temperature was

FIGS. 3, 4.—Diagrams showing the position of the heart, liver, and spleen in two cases of dextrocardia (Deutsch. Arch. f. klin. Med., Oct. 25, 1895).

37.5° C. The patient died suddenly after catheterization. The autopsy showed a rupture in the anterior wall of the left ventricle. The heart increased in size, and the whole was bulged out somewhat in the form of an aneurysm. A thrombus was found in the descending branch of the left coronary artery, and the aorta and smaller branches were atheromatous. The heart-muscle surrounding the rupture was yellow and necrotic. Tanner[2] reports an exceedingly interesting case. There was a history of a slight slip upon the ice 6 hours previous to the occurrence of pain, the latter coming on suddenly. At first there was nausea, which was relieved by an emetic, and a few hours later partial collapse, which was promptly relieved by stimulants. The pain continued for some days, gradually growing worse, and was described by the patient as a gnawing at the heart. Repeated examinations of the liver, chest, and heart revealed nothing except a dulness of the valvular sounds. In the last days chloroform and then large doses of morphin were used with temporary relief. Death occurred on the 8th day. During the course of the case the pain seemed to disappear when his attention was otherwise occupied. The pericardium was adherent to the ventricle by several fibrous adhesions. The wall of the left ventricle was thin and sunken toward the apex, and a hole the size of a knitting needle was found in it $1\frac{1}{2}$ in. from the apex and the same distance from the septum. Over this was a clot more or less stratified, adherent to the walls and filling a third of the cavity. There was thrombosis of the left coronary artery.

Embley[3] reports a case presenting a peculiar high-pitched musical sound

[1] La Presse méd., Mar., 1896. [2] Boston M. and S. Jour., 1895.
[3] Australian Med. Jour., Aug. 20, 1895.

continuous throughout the entire cardiac cycle. The heart was enlarged, but no definite murmur was made out. There were pain and numbness in the left arm, and a slight hemiplegia had existed. Subsequently dyspnea developed and death occurred suddenly. At the autopsy an **aneurysmal dilatation** of the posterior wall of the left ventricle was found, from which perforation into the pericardium had occurred. Embley believes that the gyrations produced in the blood retained in the aneurysmal sac produced the peculiar sound.

Samguine[1] reports a case of acute articular rheumatism without at first evidence of cardiac lesion, but at the 6th day there was intense pericardial pain, and a pericardial friction-sound developed. Four days later the patient on attempting to rise fell back, and in a few minutes was dead. At the post-mortem about 1 quart of blood was found in the pericardial sac, which was covered with shaggy lymph. In the posterior aspect of the left ventricle there was a small ulcer, in the lower part of which a small opening traversed the thickness of the myocardium. The valves of the heart were normal.

Cardiac Syphilis.—Jacquinet[2] refers to the rarity of cardiac syphilis. Up to the present 102 cases have been recorded, but of these not over 61 are trustworthy and complete. The myocardium is the most frequent seat. The valves are usually free. The actual lesions are gummata of the myocardium, varying in size from a millet-seed to a pigeon's egg, and a fibrous myocarditis, the latter leading to marked insufficiency of the heart. The symptoms are in general those of myocarditis from other causes. The author refers to attacks of pseudoangina occurring during secondary stages and due either to anemia or to the circulation of some poison. He refers, however, to asthmatic attacks and precordial pains as symptoms of genuine cardiac syphilis.

Loomis[3] contributes a paper on syphilitic lesions of the heart with a report of 4 cases. From his experience and the study of the literature he classifies these affectious as—1. Gummatous, in which case there may be recent soft reddish or grayish masses or older dry yellow and cheesy nodules; 2. Fibrous myocarditis, which may be localized, occurring as well-defined masses of large size, or diffuse and accompanied by inflammation of the arteries; an intermediate type occurs in the outer zone of gummata where fibrous tissue may develop around the cheesy center; 3. Amyloid degeneration; 4. Obliterating endarteritis is a less important syphilitic affection. Among the 4 cases reported, 3 were instances of gumma, the first occurring in a man of 35 who had died suddenly in apparent health, and in whom the only lesion discovered post-mortem was a large mass in the anterior wall of the left ventricle; the second being a young woman who had contracted syphilis three years before; and the third a woman who had become infected two years previously. The lesions in both of these latter cases were similar in situation and type. The author notes that the occurrence of cardiac failure in the prime of life and in the absence of rheumatic history, of valvular disease, arterial changes, or kidney complications, should lead to the suspicion of syphilis in persons giving syphilitic

[1] Presse méd., No. 15, p. 91. [2] Gaz. des Hôp., No. 93, p. 917.
[3] Am. Jour. Med. Sci., Oct., 1895.

histories. Rapid improvement and amelioration of the cardiac symptoms following appropriate treatment is important in the diagnosis. [Undoubtedly, as the author states, the role of syphilis in the production of cardiac disease has received less attention than it deserves, and the frequency of syphilitic heart-disease is probably not as yet appreciated; on the other hand, it is likely that some of the instances in which gummata have been suspected and diagnosed have been instances of myomalacia with indurative changes of the peripheral zones or surrounding the necrotic focus.]

DISEASES OF THE ARTERIES.

Atheroma.—Weber[1] contributes an article on the relations of **syphilis and atheroma.** He first points out the striking fact that aneurysms are more frequently caused by syphilitic disease of the arteries than by ordinary atheroma. Further, he holds that atheroma in itself is merely a degenerative process, though often preceded or accompanied by inflammation. Syphilis or other inflammation may, therefore, locally predispose to atheroma.

Dickinson[2] in his lectures upon the cardiovascular changes of renal disease contributes certain statistics from the study of cases of different sorts, which show that the entire cardioarterial system undergoes progressive hypertrophy from the beginning to the termination of renal disease. These changes affect the smallest vessels, the heart, and the intermediate channels in practically the same degrees.

Durr[3] refers to the **diagnosis of chronic aortitis.** Among the significant symptoms is deep-seated retrosternal pain. The direction in which this pain radiates he believes may be utilized to determine the extent of the atheromatous process. When the disease is in the neighborhood of the coronary arteries the pain runs to the heart-muscles; when the arch of the aorta is involved the extension is toward the upper extremities or the head. A very characteristic symptom is a peculiar fear of death, without disturbance of the respirations, but the most characteristic symptoms are the increase of dulness to the right of the sternum in the second interspace and the accentuation of the second heart-sound.

Boehle[4] records 2 cases of diseases of the aorta which he considers as instances of syphilitic disease. The lesions resemble those found in a previous case reported by him. The most marked characteristic was scar-formation in the media with retraction of the intima. The primary alteration he finds is round-cell infiltration around the bloodvessels of the media and adventitia. Nowhere did he find ruptures of the media.

Aneurysms.—Souchon[5] contributes an excellent review of the subject of multiple aneurysms in the same patients. We must refer to the original paper for the details. Clark[6] reports a case of varicose aneurysm communicating with the aorta and superior vena cava. The symptoms began suddenly, no

[1] Am. Jour. Med. Sci., May, 1896.
[2] Lancet, July 20, 1896.
[3] France méd. et Paris méd., No. 32, 1895.
[4] Deutsch. Arch. f. klin. Med., Bd. lv.
[5] N. Y. Med. Jour., Nov. 2, 1895.
[6] Lancet, Jan. 18, 1896.

signs of aneurysm having previously existed, and the patient remained alive one month. The right arm and the face and neck and upper part of the chest were edematous, while the left arm and the left side of the chest were not so. The author explains this by the assumption that there had been sufficient time for collateral circulation. Cavazani[1] refers to the lateral movement of the trachea (Cardarelli's sign) as an indication of aneurysm. The longitudinal movements (Oliver's tracheal tugging) is less significant. The author reports a case of marked hypertrophy of the heart with aortic insufficiency and a double mitral lesion in which tracheal tugging was present, but Cardarelli's sign was absent, and 2 cases in which aneurysm existed and in which the latter sign was well marked.

Bignoni[2] reports a case of aneurysm of the thoracic aorta successfully treated by **Macewen's method** of introducing needles into the sac so as to project on the inner wall and form the starting-place for a clot. The case was that of a farmer aged 68, who presented a rounded pulsating tumor on the right side of the sternum which had all the evidences of aneurysm, the walls being evidently quite thin. The case was referred to Sacchi for surgical treatment. He introduced 2 needles on the 30th of November, removing them after 24 hours; needles were subsequently introduced on the 4th, 6th, and 10th of December. Even after the introduction of the first needle there was notable increase in the consistency of the tumor, while the size decreased, becoming eventually one-third of the original size. On the 10th of January the last needle was introduced, as there was one point where the tumor was soft. In introducing this it was noticed that the needle met with a resistance as if it were passing through a fibrous and partly calcified tissue.

Stenosis of the Aorta.—Flint[3] records a case of narrowing of the arch of the aorta. The patient, a man of 21, entered the hospital complaining of hematemesis which had begun 2 days previously. Physical signs of phthisis were wanting, but a distinct systolic and diastolic murmur replaced the heart-sounds. The pulse was typically collapsing in character and capillary pulsation was easily developed. Postmortem examination showed that in addition to the lesion noted the aortic valves were almost completely destroyed by ulcerative endocarditis. Immediately above the valves was found a diverticulum fully 1 in. in depth, projecting as a polypoid mass into the cavity of the right auricle, while the stenosis already alluded to was seen at the junction of the transverse and descending aorta, and was so narrow that it barely admitted a small probe.

Embolism and Thrombosis.—Oestreich[4] reports the case of a young man of 32 who died suddenly of embolism of the coronary arteries. Postmortem a large pedunculated thrombus was found in the aorta, and was doubtless the source of the embolism.

[1] Gaz. degli Osped. et delle Clin., No. 84, 1895.

[2] Resoconti clin. Statist. degli Ospedali di Genova, 1894; Centralbl. f. innere Med., June 6, 1896.

[3] Lancet, Sept. 28, 1895.

[4] Centralbl. f. innere Med., 1896, No. 2.

Finny[1] reports a case of cardiac insufficiency, the patient dying very suddenly. At the autopsy the sinus of Valsalva and the beginning of the left coronary artery were found filled with a clot which could be traced along the artery for two inches.

Vasomotor Edema.—Tchukoff[2] discusses a condition of general edema without albuminuria due to vasomotor disturbance. He has observed 6 cases, all men between the ages of 25 and 60 years. There were 2 varieties, the acute and the slow. In the latter the anasarca developed slowly, requiring 3 or 4 months. In the former serious symptoms might occur in the course of a week, with the appearance of liquid in all the serous cavities. The hair was liable to fall out. Albumin was never found in the urine excepting when there was extreme ascites. The blood exhibited an unusual quantity of reduced hemoglobin, but was otherwise approximately normal. The other organs were normal, excepting that the right heart was frequently dilated and that there existed a moderate degree of arteriosclerosis. After recovery the patients were much emaciated. Tchukoff believes that the cause is some profound disturbance of the vasomotor mechanism, frequently due to an old syphilis, and almost invariably treatment with mercury or iodid of potassium gives brilliant results.

DISEASES OF THE THYROID GLAND.

Acute Thyroiditis.—Bradshaw[3] reports a case of acute inflammation with swelling of the thyroid gland. It subsides without suppuration, although at one time the symptoms of dyspnea were alarming.

Goiter.—Dock[4] notes the frequency of **goiter in Michigan,** having been struck by the common occurrence of this disease in his clinical experience in that State as compared with the number of cases observed in Philadelphia or Galveston, where his material had been more abundant. Communications from various physicians in the State showed the very great prevalence of the disease. Thus in Calumet there were found 50 well marked cases in a population of 14,000, while at the Central Mission, a few miles away, 10 cases occurred among less than 2000 people, and in Adrian 30 cases were found in a population of less than 9000. In Gaillard, Otsego Co., Dr. Parmeter reports that one-fourth of the children born in that place and reaching puberty have goiter; 52 reports give a total of 477 cases, not including those in the copper region, and though the figures do not compare with those found in the goitrous regions of Europe, the disease is evidently quite prevalent. Morris[5] reports that in Hamilton, England, with a population of 2000, he has seen 55 cases of goiter. The soil is excessively chalky, and the water-supply is obtained from deep wells sunk into the chalk.

Munson[6] in a study of goiter **among the Indians** of the United States sums up the following as the salient points: There is a strong regional predis-

[1] Dublin Jour. of Med. Sci., Apr. 1, 1896.
[2] Rev. de méd., Aug. 10, 1895.
[3] Med. Rec., Nov. 2, 1895.
[4] Med. News, July 20, 1895.
[5] Brit. Med. Jour., July 16, 1895.
[6] N. Y. Med. Jour., Oct. 26, 1895.

position to goiter among the Indians, the Crows, Menoninees, and Northern Cheyennes being particularly predisposed. Goiter is a distinctly localized disease, and appears to be uninfluenced by the high altitude, climate, or water containing calcium salts. Unsanitary surroundings, depressing conditions, and improper and excessively nitrogenous diet, with hereditary influences, are prominent causes. Sex and puberty exert a strong influence. The tumor is smaller than among the white races, and locality appears to affect the growth of the tumor as well as its frequency.

Sabrazes[1] records a case of simple goiter in which, after failure of the iodin-treatment, the use of a glycerol extract of the thyroid gland resulted in complete cure.

Stabel[2] in a study upon the value of **thyroid treatment** in goiter and in Graves' disease has found that the fresh glands selected with care and preserved on ice do not give rise to the toxic symptoms so frequently reported of late and referred to by the name thyroidism. In 25 cases of simple goiter of parenchymatous and fibrous character improvement was noted in 23, while in 2 the disease seemed completely arrested or cured. The treatment must, however, be continued to maintain the results obtained. Subsequently he employed tablets of thyroidin, and found it considerably less advantageous than the fresh glands.

Winkler[3] contributes a résumé on the use of thyroid extract as a method of treatment, and concludes that it has been useful in ordinary struma, but uncertain in Graves' disease. The tablets of extract seem less likely to cause unfavorable results upon the heart than the fresh thyroids.

Holmes[4] contributes an interesting paper upon sporadic goiter. We note only the statistical portions bearing upon the effect of different forms of treatment. The author recommends injections of iodin, and the statistics certainly bear out his claims.

DISEASES OF THE GASTRO-INTESTINAL TRACT.

DISEASES OF THE PHARYNX AND ESOPHAGUS.

Sticker[1] finds that **chronic pharyngitis** associated with dry pleurisy is always due to one of two causes, either syphilis or tuberculosis. In a first group of 4 cases each of the patients suffered from tubercular heredity, and had dry pleural friction sounds with the other characteristic symptoms, associated with exacerbations of chronic pharyngeal inflammation. In regard to his second group, comprising cases of pharyngitis in association with syphilis, he urges more liberality in accepting signs of hereditary syphilis. In particular, he holds that deformities of the teeth of various kinds are to be regarded as syphilitic when the teeth of both parents are found to be well formed and normal. Further, he considers it an important sign of syphilis if, after a number of normal children, others are born showing signs of degeneration, such as imperfect development, deformities of the nose, and discolorations of the skin, or if the first child is particularly weak and the others approximate more and more closely to the normal. He reports, in all, 9 cases of this combination, in all of which the disease of the pharynx had, according to the history, arisen without any external cause or injurious influence from environment.

Gourtade[2] reports 3 cases of **dysphagia,** in all of which local patches of **mycosis** were found either at the base of the tongue or upon the lingual tonsil, cure following their removal.

Dionisi[3] reports a case of a patient who came under his observation complaining of pain in the pharynx and later in the epigastrium. On examination pharyngitis, bronchopneumonia, and albuminuria were found. Three days later the patient died in coma, and a condition of **croupous esophagitis** was discovered postmortem. Bacteriologic examination showed the presence of streptococci, and the author concludes that the condition was similar to what is known as **croupous gastritis.**

Fränkel[4] records a case of **tuberculosis of esophagus** in which disseminated nodules were found. The infection had been conveyed through the circulation.

Johnson[5] reports 2 interesting cases of **esophageal stenosis.** The first was apparently a pure neurosis, and always worse when the patient was anxious or frightened about taking food. He was cured by the bromids, electricity, and dilatation. The second case was that of a tinsmith, aged 62, who had suffered for 30 years from dysphagia. There was frequent vomiting, the matters being sometimes mixed with blood. It was impossible to introduce a sound. At the autopsy the walls of the esophagus were found to be dilated for its whole length until just above the cardiac orifice, where there was a stricture apparently fibrous in character, and in a sacculated dilatation above it a few shallow ulcers.

[5] Buffalo Med. Jour., Feb., 1896.

Mintz[1] reports 3 cases of cancer of the esophagus in which the chemical and motor functions of the stomach were determined, being normal in each case. In the first the esophageal obstruction was not severe enough to prevent the passage of a sound, and the gastric conditions were determined by removing the gastric contents through a tube. In the other case gastric fistulæ had been formed, and the condition of the stomach was determined through these. In one case there was slight excess of acid in the gastric juice. [In a case of complete obstruction of the esophagus under our observation the gastric functions were determined by introducing test-meals through a gastric fistula that had been established. The motor power was preserved and digestion was conducted in a normal manner.]

Rosenheim[2] contributes a further report of the use of the **esophagoscope.** The operation can only be thoroughly successful when the esophagus is cleaned of food-particles. In case of stagnation of the food due to stenosis the esophagus must be washed out. Passage of a bougie must not be practised immediately before the operation, as the blood obstructs the view. Cocain is often necessary. The author details the result of observations in 18 cases of carcinoma of the esophagus. The instrument proves specially useful when there is little stenosis on account of the secondary ulceration and tumor. It was also of advantage to localize the growth.

V. Hacker[3] refers to his experiences with the esophagoscope of Mikulicz-Leiter. The instrument is inserted with the patient sitting upright upon the table, and with the head held as far back as possible, while the operator draws the larynx forward from without. Cocain applied to the pharynx obviates spasm. After the instrument has entered the esophagus its further introduction is accomplished with the assistance of the patient, who turns and gradually assumes the horizontal position upon his back, while the operator at the same time inserts the instrument more deeply into the esophagus. The examination is finished with the patient lying upon his back, the head over the edge of the table. Careful manipulation makes the operation a safe one, and the author has had no mishap in considerably over 200 cases. Pain and difficulty in swallowing sometimes occur after the operation, but give little trouble. In only 2 cases has he found it impossible to insert the instrument. [Other references to the use of this instrument will be found below, under *Diseases of the Stomach.*]

DISEASES OF THE STOMACH.

Methods of Examination.—Salzer,[4] having discussed some of the disadvantages of the Ewald and the Leube-Riegel test-meals and of those of other writers, suggests in their place, particularly in private practice, where numerous sittings cannot be obtained, the following: Early in the morning the patient is given 30 to 50 g. of cold roast, free from all fatty and membranous parts and cut into small pieces $\frac{1}{8}$ in. wide and about $\frac{1}{2}$ in. long, 250 c.c. of warm milk

[1] Wien. klin. Woch., No. 3, 1896.
[2] Deutsch. med. Woch., No. 50, 1895.
[3] Wien. klin. Woch., Nos. 6, 7, 1896.
[4] Jour. Am. Med. Assoc., Jan. 11, 1896.

or milk and water, and 30 to 50 g. of well-toasted wheat bread or Zwieback; 4 hours after this meal 30 to 50 g. of stale wheat bread without crust or toasted particles, and 300 c.c. of warm water or tea without sugar or milk. An hour later a thin, soft rubber tube is inserted and allowed to fill with the fluid. When the latter appears at the upper end, the tube is carefully withdrawn and its contents collected in a porcelain dish. If the liquid flows freely from the tube *in situ*, more may be obtained. If residue of the first meal is still present, he takes it as an indication that the digestive function is more or less impaired. The material may then be subjected to the usual tests. [The method does not seem to offer any particular advantages and is not free of deficiencies.]

Talma[1] recommends the use of meat-broth instead of test-breakfasts and test-dinners for the study of gastric secretions. The advantage of this is that it does not enter into combination with the organic and inorganic acids, and it suffices to stimulate sufficient secretion to give reliable results. The patient receives a solution of 3 g. of Liebig's meat-extract in 1 l. of water. The solution is neutralized and administered warm. An hour later the gastric secretion is expressed, the patient in the mean time having been in a reclining position with the surrounding temperature comfortable. Under the normal conditions the acidity at this time will be found to correspond to 1% of HCl.

Determination of Hydrochloric Acid.—Strauss[2] has studied the value of Töpfer's reagent for the quantitative estimation of HCl. The method is a simple one, but is not certain, on account of the difficulty of distinguishing the color-changes caused by minute quantities. Like the 1% watery solution of Congo-red, it is more delicate than Günzburg's reagent or Congo paper. Strong solutions of phosphates (½%) cause changes of color similar to those produced by weak HCl, and organic acids give a result with both solutions. The author concludes that the Congo solution is more delicate than Töpfer's reagent. Because of the difficulty in determining absolutely the substance causing the reaction, he prefers Congo paper. Hoppe-Seyler[3] has studied the same method, and holds that in spite of its somewhat indefinite end-reaction it is practically useful. Einhorn[4] has investigated the value of Töpfer's method as a test for HCl in the stomach-contents. Töpfer regards the reagent as a most delicate test for HCl, and one not influenced by organic acids, excepting lactic acid in quantities above 0.5%. Friedenwald corroborates this statement. Einhorn finds the test more delicate than Günzburg's solution, as it responds when HCl is present in the proportion of 1 to 50,000. Combined HCl does not influence it. Lactic acid, however, gives the same response if present in proportions of 0.1%. Töpfer's reagent may be used as a quantitative test if HCl is present and lactic acid absent. Five c.cm. of the filtrate are taken, and a drop of a 1% solution of phenolphthalein and ½% solution

[1] Nederl. Tijdschr. v. Geneeskunde, 1896, ii. p. 416.

[3] Münch. med. Woch., No. 50, 1895.
[4] N. Y. Med. Jour., May 9, 1896.

of Töpfer's reagent are added. The mixture is titrated with decinormal sodium hydrate solution until the red color disappears. This indicates the quantity of HCl; then further titration is practised until the red color reappears. The total number of c.cm. of soda solution used up to this time indicates the total acidity.

Simon[1] has investigated the relation between the quantity of indican and the character of the gastric juice. He finds that there is excessive indican when the hydrochloric acid is deficient or wanting. When there is hyperacidity the amount of indican is normal or subnormal, excepting in case of ulcer of the stomach. When there is abundant lactic-acid formation in the stomach in the absence of hydrochloric acid, indican is not increased.

Matthieu and Trehen[2] believe that there is a relation between the **acidity** of the gastric juice and that **of the urine,** the latter increasing with the former. For a few hours after ingestion of food the urinary acidity is decreased, sometimes with a preliminary temporary increase; and if a considerable quantity of acid is removed from the stomach either by vomiting or lavage, the urine may even become alkaline. The urine of cases of hyperchlorhydria contains more acid than cases of hypochlorhydria.

Lactic Acid.—Strauss[3] employed the following modification of Uffelmann's method: A closed separatory filter is used; 5 c.cm. of gastric juice and 25 c.cm. of ether are placed in it and shaken. The gastric juice is then allowed to flow off, and the ether is again shaken with water containing a few drops of weak (10%) solution of officinal chlorid-of-iron solution. With 1% of lactic acid an intense green color is produced; with 0.5% a paler green occurs. The method is reliable as indicating quantities of lactic acid large enough to be considered important.

Oppler[4] has proposed a method for **estimating the activity of the pepsin** in the stomach. An hour after a test-breakfast the contents of the stomach are excreted and the organ washed with distilled water. The washings and stomach-contents are diluted up to 1 or 2 liters. Diluted hydrochloric acid is added until the total acidity stands at 77. The nitrogen of a 0.2% albuminate solution is then estimated by Kjeldal's method, and 20 c.c. of this solution added to 50 c.c. of the stomach-contents and digested for 3 hours. After the precipitation of the undigested albumins, acid-albumin, etc., the nitrogen of the digested portion is estimated and the percentage of albumin thus calculated. The author obtained values for normal individuals, and found those in chronic gastritis much diminished. The same thing was found in gastric carcinoma, particularly when the body of the stomach was affected. When the pylorus was involved pepsin was sometimes present, though hydrochloric acid had disappeared. Diminution of pepsin occurs in atony, and dilatation of the stomach only when mucous catarrh with lessened acid secretion is present. Increased pepsin occurs in ulcer, acid gastritis, chronic gastrosuccorrhea, and occasionally in chlorosis. Pepsin-secretion as measured

[4] Centralbl. f. innere Med., Feb. 1, 1896.

by the activity of the pepsin seems to run parallel with the secretion of hydrochloric acid. The author thinks, therefore, that the quantitative estimation of pepsin need hardly go into general use.

Strauss[1] has studied the alterations which occur in the **specific gravity of the gastric juice** in various conditions and in health. The density of the liquid is lower when the unaltered gastric juice is predominating, and grows greater with the subsequent admixture of the products of digestion. The physiologic limits, 1 hour after the test-breakfast or $2\frac{1}{2}$ or $3\frac{1}{2}$ hours after a test-dinner, lie between 1010 and 1020. A specific gravity below 1010 is particularly frequent in cases of hyperacidity, hypersecretion, and fermentation; that above 1020 practically only in cases of subacidity.

Meinert[2] questions **the value of illumination** as a mode of diagnosis in diseases of the stomach. In particular, he doubts the reliability of the deductions made by Martius and Meltzing, and holds that the position of the lamp in the stomach and the condition of the coils of intestines exercise a decided influence on the apparent size and shape of the stomach. Comparing results obtained by illumination with those secured by palpation and measurement of the capacity of the organ, he came to the conclusion that the diophane is not reliable, though it may serve a useful purpose in locating tumors of the stomach or vicinity or displacement of the spleen. Kuttner[3] denies the assertion of Martius and Meltzing that the position and shape of the stomach may be determined with a gastrodiaphane when the stomach is empty or only partly filled. Under these conditions the light may be conducted through neighboring coils of intestine or the abdominal walls. The stomach should be filled completely, when a reliable result may be obtained. He further denies the advantage claimed for illumination in the differentiation of gastric dilatation and gastroptosis. The movability with inspiration, which Meltzing claims to be greater in proportion to the degree of apposition with the diaphragm, Kuttner holds is independent of this.

Turck[4] describes his **gyromele,** which consists essentially of a stomach-tube with a rotating center which can be set in motion by a suitable apparatus. If furnished with an ivory bulb, it can be used for determining the size of the stomach, and if with a sponge, for cleansing purposes and massage of the walls. He has also contrived a gastric motor meter consisting of a small oblong rubber bag which may be inflated after insertion and then connected with a manometer. It indicates the character of the movements and the number of the movements per minute and the degree of energy. Boas[5] has recently used the apparatus of Turck for the determination of the outline of the stomach, and in 25 out of 30 cases has found it an efficient aid. [We cannot convince ourselves that this instrument may be safely used. The danger of injury to the mucous membrane is not inconsiderable when a soft stomach-tube is employed, and is much increased in the case of such an apparatus as that referred to.]

Rosenheim [1] in discussing the use of the **gastroscope** states that in 70% of his cases the straight instrument was introduced into the stomach without difficulty or after overcoming very little resistance. The patient is placed flat on his back and the pharynx is cocainized. The operation is most apt to prove difficult in neurasthenic persons or persons presenting considerable obesity. Sometimes the preliminary use of the stomach-tube may serve to make the subsequent employment of the gastroscope easy. Occasionally slight angulation at the end of the instrument or a corkscrew-like curve of the last 7 to 10 cm. may render the introduction more easy. In the discussion of Rosenheim's paper Pariser exhibited an instrument constructed at his suggestion some time previously, and stated that it is his view that the only indication and use for the instrument is in the diagnosis of pyloric cancer in doubtful cases. He referred also to the dangers supposed to exist in some cases. As far as the use of the instrument in esophageal investigation is concerned, he notes the experience of v. Hacker, who was able to remove foreign bodies with the aid of this instrument. Ewald in discussing the paper particularly questioned the safety of the procedure, and Rosenheim in concluding admitted that certain dangers exist, though he called attention to the fact that dangers also exist for the passage of stiff instruments of any kind for exploration or diagnosis.

Moritz [2] has made studies of the **intragastric pressure** with the aid of a specially constructed mechanism. There is a constant positive pressure in the stomach, which is partly due to the contraction of its own walls, but largely to the pressure of surrounding viscera. The pulsations of the heart and the inspiratory sinking of the diaphragm cause increase of the pressure. When inspiration is performed by elevation of the lower ribs there may, contrarywise, be a diminution of pressure. The stomach is divided in its physiologic functions into the pyloric region and the fundus. In both portions there are elevations of pressure, but in the fundus the contractions are regular, wave-like, and weak. These serve to convey the liquid portions to the antrum and through the latter, while the solid matters are retained to be further acted upon. The muscular contractions of the pyloric portion are, on the contrary, very active.

Relations of Salivary Digestion.—Burger [3] has studied the activity of salivary digestion and the relation of this to local and general conditions. The patient was given a biscuit which he chewed for a minute, and the mass was then treated with 0.27% HCl or water (50 c.c. of either), according as the amylolytic action was to be stopped or to be allowed to proceed further. The amount of action was then determined by the polariscope. He found that neither the amount of saliva, the condition of the teeth, the state of the general health, nor the greater or less active HCl secretion had any influence upon this salivary digestion. It therefore appears that the latter is independent of disturbances of the gastric functions.

Robertson [4] finds that saliva and gastric secretion, mixed with a solution of

[1] Deutsch. med. Woch., No. 45, 1895.
[2] Zeit. f. Biol., Bd. xxxii. H. 3.
[3] Münch. med. Woch., No. 10, 1896.
[4] Edinb. Med. Jour., May, 1896.

starch when there is 0.05% of hydrochloric acid in the gastric contents, leaves the starch unchanged after 2 hours. If the mixture be carefully neutralized, the starch is wholly converted within 10 minutes. This was true as well of the secretion from the normal stomach as of that obtained from cases of chronic gastric catarrh. When the gastric secretion alone was mixed with the starch-solution no conversion occurred either with the secretion of a healthy stomach or the secretion of a stomach affected with chronic gastric catarrh, but when the secretion from a case of pernicious anemia was taken, it was found that in a mixture of 30 c.c. 1% starch solution, and 10 c.c. of the unhealthy gastric secretion with an acidity of 0.016% HCl, at the expiration of 1 hour 0.6% of reducing-substance was present. When the starch-solution was introduced into a healthy stomach, care being taken that no saliva was mixed with it, after the lapse of an hour considerable starch was still present, although there was also a trace of reducing sugar, and erythrodextrin was found in considerable amount. After 2 hours the starch had practically disappeared and there was no erythrodextrin or sugar. The effects in the case of chronic gastric catarrh were similar but slower. In the case of pernicious anemia, however, at the expiration of 1 hour the quantity of reducing sugar amounted to 1%; an hour later this had completely disappeared. These results were repeated, and saliva was mixed with the starch before it was injected into the stomach, it appearing that the acid completely inhibited the action of the reducing agent of the ptyalin, and when the gastric contents were withdrawn and neutralized no further reduction took place. Robertson concludes from this that even a short stay in the stomach during the digestion of a simple carbohydrate suffices to completely destroy the ferment of ptyalin.

Hamburger[1] studied the action upon starch of the saliva, pancreatic and intestinal juices, and the blood. He used the saliva of man, the pancreatic and intestinal secretions of dogs, and the blood of bullocks and dogs. One c.cm. of either of these was allowed to act upon 50 c.cm of a 1% potato-starch solution at 30° C. After 24 hours the amount of decomposition, estimated as glucose, is determined. These figures are—saliva, 0.3; intestinal juice, 0.26; pancreas, 0.36; and blood, 0.80. The maximum in the case of saliva is reached within an hour, with the blood in 24 hours, with the pancreatic juice in 45 minutes, and in cases of intestinal juice less rapidly even than in case of the blood.

Changes in Form and Position of the Stomach.—Meinert[2] contributes an elaborate article upon the normal and pathologic positions of the stomach and the methods of determination. In the new-born child the stomach occupies a vertical position, but it soon assumes the position described by Luschka, and so remains through life, unless it is influenced by defective condition of the thorax or abdomen or by improper clothing. After the 6th year the vertical position of the stomach is again noticed in increasing proportion with increasing age, especially in girls. The alteration is particularly rapid between 11 and 15, and of 50 girls examined at a public school at the age of

[1] Pflüger's Arch., Bd. lx. p. 543. [2] Centralbl. f. innere Med., Mar. 21, 28, 1896.

12, almost half presented dislocated stomachs. Among girls of 14 examined, he found **gastroptosis** in 80%, and among the women presenting themselves at his private gynecologic clinic, 90% presented gastroptosis. On the contrary, he estimates that this dislocation occurs in but 5% in the male population of Dresden. The cause of this dislocation is found in improper clothing, and particularly in tight lacing. Abnormalities of the chest-conformation may contribute, and other causes are occasionally active. Regarding the position of the stomach in gastroptosis, the author points out that the cardiac end remains fixed at the 12th dorsal vertebra, while the pylorus moves downward, leaving the epigastrium free of gastric tympany. Regarding the method of demonstration, he holds that that of distention with gas by the use of effervescent mixtures or by direct inflation with atmospheric air gives the most satisfactory results. Direct percussion or percussion after water has been allowed to flow into the stomach permits no accurate differentiation of dilatation from dislocation, and the methods of illumination he holds, with Boas and others, as elusive on account of the danger of transmission of light through adjacent coils of intestine. The method of inflation is a special advantage in demonstrating the lesser curvature and indicating the position of the pylorus, thus at once distinguishing between dislocation and actual dilatation. The position of the stomach during life, but not its size, may be accurately verified postmortem. [We are disposed to agree with many of the author's statements, though we cannot believe that dislocation of the pylorus is as frequent as he states. It has certainly not been our experience to find the vertical position or gastroptosis as frequently in American girls and women as he has found in the Germans. The value of inflation of the stomach is not, we believe, overestimated in the least. For several years we have used this method in our practice and as a means of clinical demonstration.]

Schwerdt[1] in a study of 95 cases of **enteroptosis** found that 89 occurred in women and but 6 in men. The stomach was displaced and atonic in 69 cases. The kidneys were also affected on the right side in 86 and on the left in 4. In 18 cases the abdomen was pendulous, in 11 the uterus was prolapsed, and in 27 there was pelvic inflammation with hemorrhage. In 1 case there was total enteroptosis, except that the spleen was unaffected. In most cases the hand could be pressed into the abdomen, showing a diminished intra-abdominal pressure. In gastroptosis the system is atonic and diagnosis must be made from dilatation of the stomach. Movable liver and spleen rarely exist. Regarding the cause the author considers the following active: heredity, unsuitable habits, chronic diseases, as tuberculosis, chlorosis, hysteria, corsets, and pregnancy. The disease is not fatal, but leads to many unpleasant disturbances—notably dyspepsia, headache, palpitation, and dyspnea.

Fleiner[2] discusses at great length the **functional disturbances** produced by changes in the form and position of the stomach and colon. These dislocations of the stomach are produced either by pressure from below, such as may occur from meteorism, by artificial distortion of the body, such as is produced by cor-

[1] Deutsch. med. Woch. 23, 1896.

[2] Münch. med. Woch., No. 42, 1895.

sets, or by enlargement of the abdominal organs, such as the enlarged spleen of leukemia. Congenital dislocations, however, such as occur in cases of kyphosis or abnormally narrowed thorax, seem to produce no functional disturbance, probably because the stomach gradually learns to adapt itself to its altered condition. Frequently, in women, the first result of the compression of the corset is diminution of the size of the stomach. This prevents the ingestion of sufficient nourishment, and therefore the disappearance of a certain amount of food from the mesentery. As the result of this, the stomach has again room to distend and resume its normal size. These deformities, however, frequently occur in women who have never worn corsets, and are then the result of the relaxation of the abdominal walls which follows childbearing. The most important functional disturbance is the increased difficulty that the stomach has to empty its contents. Later, there is usually found a greatly diminished secretion of the gastric juice and the development of a nervous dyspeptic condition. The sinking of the colon is usually the result of very tight lacing. This produces distortion of the ascending colon, and sometimes also of the right kidney, which becomes movable; the left kidney, however, usually remains in its place. Manifold disturbances of the function result, the most important of course being constipation, produced by the difficulty of peristalsis. Colic-like pains are at the same time produced by a spasmodic condition of the intestinal muscles. In conclusion, he records 3 cases in which various conditions of dislocation of the abdominal organs existed. In the second of these there existed considerable induration all around the transverse colon, which lay rather low in the abdomen, and upon incision this was found to be a purulent pericolitis. No perforation, however, had taken place, and it was supposed that the organisms had penetrated the mucous membrane during a long persisting fecal immobility.

Schwerdt[1] contributes a study of **intraabdominal pressure occurring in cases of enteroptosis and in health.** The author distinguishes two forms of pressure in the hollow viscera—(1) that which is due to the tonic contraction of the walls of the organ, and (2) that which is due to pressure upon the organ by the surrounding structures. The former of these depends upon the muscular walls. The pressure exerted by these upon the contents is naturally increased when there is distention of the abdominal walls or increased contents in the abdominal cavity. The second form of pressure is naturally greater in the most dependent parts of the abdomen, being practically *nil* just beneath the diaphragm when the patient is erect. Studies of the pressure in the stomach, bladder, and rectum showed the pressure in the first to be 11 cm. of water; in the second 29 cm.; and in the last 39 cm. The figure 11 cm. is taken to represent the contraction-pressure in the stomach alone, since there is no gravitation-pressure from without, and, assuming that the contraction-pressure is practically the same in different parts, the total pressure of 39 cm. in the rectum may be divided into 2 parts, 11 cm. representing the contraction-pressure, and 28 cm. the gravitation-pressure or that due to the weight of the

[1] Deutsch. med. Woch., Nos. 4 and 6, 1896.

superimposed organs. Change of position of course influences the figures very much, and muscular efforts similarly increase the intraabdominal pressure. Thus, taking the former figures to represent the conditions during repose, he found the elevation to a horizontal position of 10 kg. caused a pressure in the stomach of 59 and in the rectum of 78. The latter may be taken to represent 59 cm. contraction-pressure and 19 cm. gravitation-pressure (59 + 19 = 78). This reduction from normal amount of gravitation-pressure is in accordance with deductions we might form from the effects of a severe muscular strain. Regarding enteroptosis, the author found, as we might assume, that the pressure in various positions of the body is considerably decreased. The lowest pressure was found in the rectum, the patient being in a knee-chest position, the explanation of this being that the gravitation occurs in the direction of the elastic anterior abdominal walls.

Gastritis.—Kelynack[1] reports a case of **diffuse phlegmonous gastritis.** Clinically, it was characterized by an esophageal stricture apparently of fibrous nature, persistent incontinence of food, and finally rise of temperature and collapse. At the autopsy a stricture of the cardiac end of the esophagus was found, and the lower part of the esophagus was the seat of an acute septic esophagitis. The stomach was normal in size, but the walls were much increased in thickness, and from the cut surfaces an abundant seropurulent exudation oozed out upon simple pressure. There were no signs of ulceration, new growth, abscesses, or perforation, nor was there general peritonitis. Microscopically there was considerable parenchymatous degeneration. The tissue was infiltrated with compressed short rod-like organisms that closely resembled the bacterium coli communis.

Turck[2] states that the diagnosis of **gastritis glandularis chronica** is largely made by the microscope, pieces of mucous membrane being snipped off by an instrument devised by himself, and by the careful examination of the contents of the stomach. Bacteriologically, the disease is not characterized by the presence of a single germ, but rather of a group of various microorganisms. These groups colonize in the mucous layer that adheres to the stomach-walls and produces toxins which cause the functional and pathologic phenomena of inflammation. Treatment consists of their thorough removal with the gyromele. [The author places much more reliance in the microscopic examination of bits of mucous membrane than seems justified. Nothing is more difficult than to arrive at satisfactory conclusions from such examinations. We have previously stated our objections to the instrument recommended.]

Einhorn[3] concludes, from a study of the gastric mucosa such as may be found in the wash water after using lavage, that a positive diagnosis cannot be made from it, and that it is not permissible to consider that such anatomic changes as may be found are the cause, and not possibly the result, of the functional disturbances.

Robertson[4] describes a disease peculiar to the Australian aborigines, in

[1] Lancet, Mar. 14, 1896.
[2] Med. News, Apr. 4, 1896.
[3] Med. Rec., June 27, 1896.
[4] Internat. Med. Mag., Oct., 1895.

which the stomach becomes perfectly hard and gradually enlarges enormously. The body wastes, while the appetite is voracious, with an especial craving for meat, though the patient can eat but little at a time, when the food does not seem to nourish. The course is slow and ends in death. No postmortem has ever been obtained.

Functional and Neurotic Disturbances.—Kelling[1] describes a case of **periodic vomiting** occurring in a woman of 42 whose mother and grandmother had suffered with similar attacks. Dizziness, fainting, and diarrhea, with the vomiting, were the striking features, and the attacks were preceded by edema of the limbs of fugacious and wandering character. Emotional disturbances seemed to be the exciting cause, and the author concludes that the condition is due to a hysterical vasomotor disturbance. Drugs were of no avail, though morphin lessened the severity of the paroxysms.

Debove[2] records a case of extreme **anorexia** occurring in a woman of 29. The patient had been an excessive alcoholic, but had given up this habit. Six months before her admission she had suffered with excessive vomiting, but this subsided, and for 3 months preceding her admission she had complete anorexia. There were no stigmata of hysteria, and the author believes that the underlying cause was some form of psychic disturbance. He refers to the fact that anorexia is frequently a predisposing cause of tuberculosis.

Devries[3] reports a case of **merycism** occurring in a man who was practically an imbecile and suffered from incipient phthisis. There was nausea, and the patient described the cud as being somewhat sweet with an acid taste like lemonade without lemon. Immediately preceding the regurgitation movement of the stomach could be felt. These were further assisted by the contractions of the diaphragm and abdominal muscles. As a measure of treatment he produced complete narcosis by ether and continued it for 1 hour and 40 minutes. After this the symptom disappeared entirely.

Einhorn[4] makes a further report on **achylia gastrica,** as he terms the condition in which gastric juice is not secreted. The report includes some details of 10 new cases. He agrees with the systematic writers (Ewald, Boas, Bouveret) that the disease is often a form of chronic glandular gastritis, but maintains that some cases are of neurotic origin. The prognosis as to life is good, the small intestine replacing the stomach in the process of digestion. The indications for treatment are to increase the motor power of the stomach, and to arrange the diet so that it is easily accessible for the intestinal digestion. The first indication is best met by lavage or faradization or by bitters; the second, by giving the food in a finely broken condition. Vegetables and starchy food may be given in the form indicated, but meat is to be used in small quantities.

Boas[5] contributes an article on **chronic hypersecretion** or **gastrosuccorrhea.** The mere determination of large quantities of gastric juice

[1] Zeit. f. klin. Med., Bd. 29, p. 421.
[2] Progrès méd., 1895, No. 42.
[3] Indian Med. Rec., Apr. 16, 1896.
[4] Med. Rec., July 6, 1895.
[5] Berl. klin. Woch., No. 46, 1895.

does not suffice to make a diagnosis. The clinical symptoms (burning, eructations, occasional vomiting, and pain) must also be present. The stomach presents evidences of lack of motor power, and the increased quantities of gastric juice must be constant. He holds that the motor insufficiency leads to increased secretion of gastric juice on account of the irritation by the retained food; and he refers to a case of his own and one of Rosenheim's in which relief of a benign pyloric obstruction caused cessation of hypersecretion.

Schule[1] has made some investigations regarding the secretions in the **"fasting stomach."** He studied the subject in 9 cases, 6 of whom had been trained by previous experiments to swallow a stomach-tube. He found that in 31 of 34 trials the stomach contained a certain amount of liquid which was always acid in reaction, and therefore contained some gastric juice. Free hydrochloric acid was present only 7 times; bile, peptone, and pepsin occasionally. The cause of the presence of gastric juice he regards as saliva or other secretions swallowed during sleep. He has had no experience of cases of continuous hypersecretion. He would regard hyperacidity, even though the quantity of the contents was small, as pathologic, but the mere increase of quantity itself is not necessarily abnormal.

Treatment of Chronic Gastric Diseases.—Schule[2] has investigated the influence of **sleep** upon the processes of digestion, and has found that there is a distinct increase of acidity after a test-meal when the patient sleeps during the interval, as compared with the result obtained in the same person waking. At the same time there was a distinct retardation of the motor activity. The author therefore advises against sleep after meals, particularly in persons suffering with digestive disturbances with excess of HCl.

Chittenden and Mendel[3] contribute an interesting study of the influence of **alcohol** and alcoholic drinks upon the chemical processes of digestion. Their observations agree largely with those of Sir Wm. Roberts. They find that moderate quantities of pure alcohol—say 1 or 2% of absolute alcohol, corresponding with 2 or 4% of proof spirit—do not retard gastric digestion, but seem if anything to stimulate it. Large quantities—that is, more than 5 or 10% of absolute alcohol—retard digestion. The effect on pancreatic digestion was more marked; the effect on salivary digestion less so. Whiskey, brandy, rum, and gin, forms of liquors containing much alcohol and little residue, act practically the same as pure alcohol upon gastric digestion. Small quantities of fusel oil do not retard digestion. On pancreatic digestion these forms of alcohol are inhibitory, probably on account of a substance contained in the solid matter and connected with the acidity of the fluid. Wines have little effect on gastric digestion in small quantities, but retard pancreatic digestion more than the stronger liquors, and inhibit salivary activity markedly in proportion to their acidity. Malt liquors retard all forms of digestion, on account of extractive matters contained. Haan[4] has

[1] Berl. klin. Woch., No. 52, 1895.
[2] Ibid., Nos. 50, 51, 1895.
[3] Am. Jour. Med. Sci., Apr., 1896.
[4] Compt. rend. des Séances de la Soc. de Biol., t. 36, 1895.

studied the effect of alcohol upon the various functions of the stomach experimentally, using dogs for the purpose. The continued administration of large doses causes a rapid decrease of the motility of the stomach after a primary increase, and the production of HCl also falls off rapidly, while the combination of acid with albuminous bodies occurs less readily than normal.

Wroblewski[1] has studied the action of various kinds of **pepsin** under various conditions outside the body. He found that different acids varied in the degree in which they stimulated digestion. Oxalic acid was first in power, and HCl was next. Various alkaloids and alkaloidal salts exercised an influence, particularly coffee, which stimulated the digestion markedly, and veratrum, which retarded it.

Reale[2] believes that **lavage** of the stomach is indicated in all cases of chronic gastric catarrh when hypochlorhydria and atony of the stomach are present, and that cure may be obtained more rapidly by this method than by any other. The action also upon the various symptoms, such as vomiting and the subjective symptoms particularly, and upon the secretion of hydrochloric acid, is always beneficial. He reports 11 cases in which this treatment was used with excellent results. [Objection cannot be made too frequently to the routine practice of lavage in gastric diseases. While we have obtained excellent results in many cases, some are undoubtedly injured; and the stomach-tube-habit should always be guarded against.]

Norstrom[3] describes the technic of **gastric massage.** He finds that the best position is upon the right side, the left overhanging the middle line. It usually requires several seances before the patient is able to endure the maximum treatment. The results are stimulation of the muscular coats and of the glands. The treatment is particularly adapted to the idiopathic forms of dilatation produced in instances of nervous trouble, and especially in gastralgia, although in the former group of cases there is no diminution in the size of the stomach, merely a disappearance of the symptoms.

Bradbury[4] reports 7 cases of gastralgia with varying symptoms, treated with **potassium bichromate** in capsule, each containing $\frac{1}{10}$ gr. In 5 of these cases there was complete disappearance of all the symptoms; in 2 there was no improvement. He believes that the drug is a gastric tonic, but that its action may in part be due to the fact that it is an acid salt. It should be given only upon an empty stomach.

Bonnefin[5] records a number of instances of intractable vomiting treated by **faradization** of the pneumogastric nerve. He details the histories of 4 cases of this character, in all of which the treatment indicated was highly satisfactory.

Green,[6] having concluded that vomiting could not occur in an adult without fixation of the diaphragm, has devised a modified **tracheal tube** that is to be inserted in cases of persistent vomiting. This has acted well in some cases by preventing the closure of the glottis.

[1] Zeit. f. Physiol. Chemie, Bd. xxi. H. 1.

[5] Jour. de Méd. de Paris, July 7, 1895.
[6] Med. News, July 6, 1895.

Turck[1] advocates a new apparatus by means of which he is enabled to introduce a rapidly alternating **hot and cold spray** into the stomach. It consists essentially of two large bottles in which pressure is maintained by means of compressed air connected with a stomach-tube; each connection is supplied with an easily manipulating cut-off. One bottle is filled with hot water, and one with cold, and the cut-offs are opened alternately.

Pyloric Obstruction.—Manasse[2] reports an interesting case of a gastric concretion. The patient, a man accustomed to the use of alcoholics in excess, drank alcoholic solutions of shellac. At the autopsy a gastric ulcer was found, and near the pylorus a concretion of dark green color and stratified arrangement, measuring 10 by 5 by 4 cm. and weighing 75 g. Chemic examination showed this to be composed of shellac. Similar cases have been reported by Friedländer and by Langenbuch (quoted by Friedländer). [Concretions of this kind might easily lead to pyloric obstruction in the same way as peach-stones and other bodies that have been swallowed.]

Bouveret[3] records instances of obstruction of the pylorus due to **gall-stones,** pointing out that this is the least frequent of all causes, excepting congenital stenosis. The stenosis may occur from the formation of adhesions due to localized peritonitis, from spasms of the pylorus due to contraction of the loaded stomach or irritation of neighboring inflammation, from fixation of the pylorus by adhesions, and an angular bend near the pylorus due to the presence of food in the stomach, and, finally, from the presence of a large stone fixed in the duodenum. Regarding the diagnosis, the author calls particular attention to the fact that in cases in which fixation of the pylorus exists the symptoms of dilatation persist while the patient is upon his feet, but cease when he rests in bed. A history of gall-stones or of biliary colic aids greatly in the diagnosis.

Gross[4] describes a case which he regards as one of spasm of the pylorus, and suggests the term **pyloralgia.** This case occurred in a woman of nervous temperament who was subject to attacks of pain in the region of the stomach, which ceased after vomiting sour matters. In one attack, which was witnessed by himself, there was distention and violent pain over the stomach the day after injudicious diet. The attack was finally relieved by introducing a tube and removing large quantities of intensely acid material. This had a total acidity of 130 and contained excess of HCl. The author points out the differential diagnosis from other painful affections of the epigastrium, and suggests that the spasm by its continuance, whether painful or not, or by its repetition, leads to hypertrophy of the pylorus.

Dilatation of the Stomach.—Hayem[5] reports a case of dilatation of the stomach with physical signs of heart-disease. There was dyspnea with 60 respirations per minute, edema of the lungs, tenderness of the abdomen, and a rasping systolic murmur was heard in the fourth intercostal space and a curious

[1] Med. News, Mar. 21, 1896.
[2] Rev. de Méd., Jan., 1896.

[4] N. Y. Med. Jour., Mar. 7, 1896.
[5] Med. moderne, July 13, 1895.

bruit at the apex. All the symptoms disappeared after washing out the stomach daily.

Wissel [1] has investigated the **gaseous fermentation** in the stomach. A certain amount of gas consists of the atmospheric air which has been swallowed. The oxygen of this is partly used in bacterial growth or absorbed, and excess of CO_2 occurs. In most cases CO_2 and H are present in equal proportions, besides the atmospheric air. The amount of fermentation could be determined by the analysis of the gases. The more fermentation and the less atmospheric air, the more CO_2 and H and the lighter the sp. gr. of the gases. Regarding the effect of medicines, he found that creasote affects the fermentation but little; bismuth subnitrate acts similarly, but is not advisable; the salicylate and sulphite of sodium act more powerfully, but bicarbonate of sodium is most useful. The presence of HCl has little effect. The occurrence of fermentation is of no importance as an indication of lack of motor power, as there was decided fermentation without motor insufficiency in at least 2 of his cases.

Strauss [2] reports a case of gastric disorder in which putrefactive fermentation led to formation of H_2S. A careful bacteriologic study showed that the microorganism which causes this fermentation was the Bacillus coli communis. There was absence of HCl and of lactic acid. In a second case, in which pyloric stenosis was brought about by corrosive action of oxalic acid, stagnation of the food and overproduction of lactic acid were present, and the same microorganism was discovered. In a third case high-grade motor insufficiency, due to carcinoma of the pylorus, and in which free HCl, but no lactic acid, was found, considerable gaseous fermentation occurred and the same bacillus was discovered.

At the recent session of Congress of Swedish and Norwegian surgeons, held at Christiania, Borelius considered the question of **surgical treatment** of gastrectasis, and he reports the case of a man of 31 years who had a dilatation of the stomach, the organ extending to the pubis. In November, 1894, he operated, taking a reef in the wall of the stomach (suture en bourse) in the anterior and posterior wall. The patient was temporarily improved and gained 20 pounds; then lost flesh again and went down hill. In May of 1895 he performed a gastroenterostomy, which seems to have relieved the patient of all his trouble. He does not state to what the dilatation was due.

Gastric Ulcer.—Nauwerck [3] believes that microorganisms are important in the production of gastric ulcers in some cases. The matter is difficult to determine because of the likelihood of secondary deposits of bacteria. He refers to 2 cases of hemorrhagic erosions with evidence of beginning formation of peptic ulcers, in which deposits of bacteria within the walls were discovered. One of these was a case of rheumatic endocarditis, and the other a case of streptococcus infection during scarlet fever. He denies the view of Langerhans,

[1] Hoppe-Seyler's Zeit. f. physiol. Chemie, Bd. xxi., 1895.

[2] Berl. klin. Woch., May 4, 1896.

[3] Münch. med. Woch., Nos. 38, 39, 1895.

that hemorrhagic erosion and round ulcer have no relation with each other, basing his opinion upon the consideration of 37 cases.

Osler[1] records an interesting case in which a visible **contractile tumor of the pylorus** occurred with ulcer of the stomach. The patient first came under observation with unmistakable symptoms of gastric ulcer. Later a phantom tumor was noticed from time to time in the epigastrium. It would appear and disappear at intervals, remaining for from one half to a minute, and disappearing gradually, sometimes with an audible sizzling sound. It was extremely hard when distended, and when relaxed it was felt as a sausage-shaped tubular body which could be rolled about beneath the fingers. The patient died, and at the autopsy a large contracted and thickened pylorus was discovered. The wall in one place was 14 mm. thick. An area having the appearance of a healing ulcer was found within. The muscular coat of the entire stomach was hypertrophied. There was no evidence microscopically of carcinoma.

Mettler[2] describes a case of gastric ulcer remarkable for the long period during which symptoms existed; 8 years before examination the patient began to be troubled with dyspepsia, and during all this time suffered at times from a slight boring or gnawing pain which shot through to the back and was felt near the angle of the left scapula. After partaking of solid food the pain would sometimes become very acute and definitely localized. There was almost always more or less pain in the left hypochondrium, and its site never shifted anteriorly or posteriorly.

Hawthorne[3] reports 2 cases of secondary **parotitis** following gastric ulcer. The first case, a woman of 42, had had constant pain in the epigastrium with vomiting for 3 weeks, and hematemesis on the day of admission. Her health previously had been good. The symptoms subsided, but in 2 weeks elevation of temperature with right-sided parotitis developed. The swelling subsided without suppuration. The second case, a woman of 26, was admitted to the hospital on account of severe hematemesis, which was repeated 3 days after admission; 4 days after this right-sided parotitis with fever developed and suppuration ensued. The author has been able to find but 1 case in the literature in which there was undoubted gastric ulceration in association with parotitis.

Wells[4] reports an interesting case that he observed in Neusser's clinic, of a young woman 25 years of age who suffered from vomiting after meals, the vomit containing a copious admixture of blood. Examination of the blood showed that it was entirely normal, and subsequently the diagnosis of hysteria was made and confirmed by the presence of the stigmata. [The presence of blood in the vomited matters in cases of hysteria is not unusual.]

Strauss[5] advocates the administration of **sugar** in cases of ulcer of the stomach or hyperacidity, since he has found in his experimental work that the

[1] Montreal Med. Jour., Aug., 1895.
[2] Jour. Am. Med. Assoc., Feb. 22, 1896.
[3] Glasgow Med. Jour., July, 1895.
[4] Med. News, Mar. 14, 1896.
[5] Zeit. f. klin. Med., Bd. xxix. p. 221.

administration of solutions of sugar delays the secretion of HCl. The quantity given should not exceed 60 g. per day, divided in small doses.

Watson[1] records a most interesting case of **hour-glass contraction** of the stomach near the pylorus, due to the healing of a gastric ulcer. The patient, a woman of 32, had an attack of jaundice with pain in the epigastrium 7 years before. She vomited blood and was quite ill, but eventually recovered. Seven years later eructations, nausea, and tenderness developed, and finally pain and vomiting became almost constant. She lost 40 pounds in weight, was very anemic, and menstruation was absent for 6 months. An operation was done, and a cicatricial contraction was found near the pylorus. An anastomosis was made between the parts of the stomach on either side of the contraction, and perfect recovery followed.

Blume[2] describes 27 cases of gastric and duodenal **perforation** in which no operations were performed, and 17 in which some form of operation was attempted. Of the former 27 cases, 7 recovered, 16 died rapidly (1 to 10 days), and 4 after a considerable interval (1 to 3 months). Peritonitis always occurred, and the rapidity with which this became general determined the duration of life. In the cases which recovered the diagnosis was made by the occurrence of severe pain in the region of the stomach and the secondary development of peritonitis. The management of the case consisted in the administration of large doses of opium or morphin and the most carefully regulated diet, beginning, if possible immediately, with small quantities of food by the mouth. Rectal enemata were not employed. Of the 17 operated cases which he has collected, 3 were instances of perforation of the pyloric end or of the duodenum, and 1 of these recovered; 1 case involved the posterior wall of the stomach and recovered; 4 cases affected the anterior wall, of which 1 recovered; 9 cases were in the neighborhood of the cardia, and 3 recovered. [It is evident that early and carefully considered operation is always justified.]

Gastric Carcinoma.—Ebstein[3] in discussing **hematemesis** reports 3 cases in which, shortly after severe muscular strain caused by lifting heavy weights, the patients had hematemesis, and subsequently symptoms of gastric carcinoma, which in 1 case was positively confirmed by the autopsy. He believes that the injury causes a hemorrhagic infiltration of the mucous membrane or the submucosa, and that the injured area was probably digested subsequently by the gastric juice. In 1 case a severe hematemesis occurred, causing death from anemia that apparently arose from some ecchymotic patch of mucous membrane, no ulcer being found either in the stomach or in the intestines. Such cases, he believes, are usually associated with considerable enlargement of the spleen, and arise principally under the influence of general diseased conditions. In the case reported the aorta was chlorotic in type. He further reports 2 similar cases, which, however, did not terminate fatally. Another group of the causes of hematemesis is that in which general injuries of the body, such as severe falls, occasion the hemorrhage. He reports 3 such

[1] Boston M. and S. Jour., Apr. 2, 1896. [2] Nord. med. Arkiv, Nos. 4 and 5, 1895.
[3] Deutsch. Arch. f. klin. Med., July, 1895.

cases of his own with subsequent development of the symptoms of gastric ulcer, and collects 7 similar cases from medical literature. He considers that these gastric symptoms are due to disturbances of the nervous system or of the circulation, the stomach being especially liable on account of the fragility of its vessels and the corrosive quality of the gastric juice. Other causes are mechanic, thermic, and chemic injuries, among the former being the case in which he observed perforation produced by a rusty nail. Liquids at a temperature of 50° C. or more may sometimes produce gastric ulcer, but only in cases already predisposed. In all such cases, however, we are only justified in making a diagnosis of hematemesis following injury.

Kelynack[1] records a case showing the liability of ulcer of the stomach to become converted into cancer. The patient was a man of 27 years, and the author bases his views upon the fact that gastric symptoms had been present for at least 4 years, during the greater part of which time they had been typically those of simple ulcer; there was neither cachexia nor wasting, and the post-mortem showed the growth limited to the ulcer and its immediate neighborhood. It was evidently recent and rapidly growing. An actual tumor had been noticed only within a few months before death, and there was no metastasis; secondly, it had been noticed that HCl was present within a short time before death. Hoppe-Seyler[2] does not confirm Boas in his views of the value of lactic acid as an indication of carcinoma, as he has observed an instance of catarrh of the stomach with abundant lactic acid and no free HCl. This case, with others that have been observed, makes the lactic acid method comparatively valueless..

Strauss[3] reaches a similar conclusion regarding chemic methods as indicating carcinoma of the stomach. One case to which he refers, of cicatricial stenosis at the pylorus with marked motor insufficiency, showed enormous production of lactic acid, while in the second case of carcinoma of the pylorus HCl was present, while lactic acid was absent. Regarding the statement of Boas that the occurrence of lactic acid and H_2S fermentation are inversely related, the one occurring in cases in which the other is absent (lactic acid being present in malignant, H_2S in benign, stenosis), the author states that in a large number of cases of benign dilatations with gaseous fermentation he could not determine H_2S formation. Nevertheless, he does not entirely deny the justification of Boas's assertion.

DISEASES OF THE INTESTINES.

Constipation.—Romine[4] has practised forcible dilatation of the sphincter ani in a number of cases of chronic constipation, 4 of which he reports in detail. The results are usually excellent.

Merkle[5] has found insufflations of **boric acid,** introduced by the ordinary

[1] Brit. Med. Jour., Jan. 18, 1896.
[2] Münch. med. Woch., No. 50, 1895.
[3] Berl. klin. Woch., May 4, 1896.
[4] Therap. Gaz., Sept. 15, 1895.
[5] Münch. med. Woch., No. 52, 1895.

powder-blower, useful in the treatment of intestinal atony with flatulence and constipation. From 30 to 60 gr. of boric acid are thus introduced.

Lauder-Brunton[1] suggests the use of **opium** in cases of constipation arising from abdominal irritation.

Intestinal Obstruction.—Kidd[2] has seen 7 cases occurring in women in which symptoms indicative of intestinal obstruction were associated with movability or displacement of the right kidney. The pressure exerted upon the ascending colon is supposed to be the immediate cause. In addition to this, the nervous influence through the suprarenal and mesenteric plexuses may play a part in the causation. [It has been denied by a number of authors that a movable right kidney can exercise sufficient pressure upon the intestines to cause obstruction. Though we have seen no case in which the colon was obstructed, we have met with several in which dilatation of the stomach seemed to be due to compression of the duodenum by a floating kidney.]

Schietzler[3] reports 2 cases of obstruction of the intestines due to **pressure of the mesentery.** Three cases of similar character have been reported by Kundrat, and the latter explains the condition upon the ground that the mesentery, instead of having the form of an open fan, is like a fan only partially opened. In the downward descent of the intestines, therefore, pressure is exerted upon the duodenum by the edge. Abdominal relaxation is usually the cause of this form of obstruction. Jordan[4] describes a case in which intestinal obstruction was due to **persistent ductus omphalomesentericus.**

De Jolinière[5] calls attention to the symptoms and disturbances which may result from **peritoneal adhesions.** Grave forms of disease may be simulated in such cases, and in particular adhesions of the stomach may produce intense stabbing or dragging pains, vomiting, and dyspeptic symptoms. The pain is usually relieved by the discharge of the food by vomiting, and is absent when the stomach is empty. Intestinal adhesions are similarly characterized by pain, while attachments to the gall-bladder may occasion manifestations resembling biliary colic.

Rolleston and Hayward[6] report the case of a boy aged 12 who suffered with chronic **dilatation of the colon.** He had been constipated since 6 months of age, and the abdomen was greatly distended. Peristaltic waves were visible upon the surface. The condition varied greatly from time to time, the abdomen sometimes being soft and the bowels acting daily; at other times constipation and vomiting would suddenly occur. Treatment was ineffectual, and the patient died. Postmortem great distention and ulceration of the colon were discovered. No stricture or obstruction was seen. [The case resembles the remarkable instance of "giant-colon" reported by Formad, and 1 recently observed by one of the editors.]

Diarrhea.—Pollatschek[7] discusses the value of rectal injections of warm

[1] Lancet, May 30, 1896.

[3] Wien. klin. Rund., Nos. 37 and 38, 1895.
[4] Berl. klin. Woch., 1896, No. 2.
[5] Jour. de Méd., Apr. 25, 1896.
[6] Brit. Med. Jour., May 30, 1896.
[7] Wien. med. Woch., May 9, 1896.

natural saline solutions in severe cases of chronic diarrhea. He commences with 100 c.cm., and never exceeds 200, the temperature ranging from 42 to 45° C. This treatment is particularly indicated in curable ulcerative processes. It acts as a sedative, and to a certain extent promotes healing. Musser[1] reports a case of primary carcinoma upon the superior maxilla, with secondary carcinoma of the bones and multiple fractures, death occurring from hemorrhages due to **duodenal ulcer.**

Appendicitis.—Roger and Josué[2] have reported some experiments on rabbits regarding the pathogeny of appendicitis. They injected cultures of the bacillus coli into the appendix and then ligated it, producing suppurative appendicitis. Later they found that simple ligature sufficed, and in the dilated appendix resulting they found the bacillus coli in pure culture. These microorganisms, therefore, while repeatedly found in the appendix, are inoffensive until occlusion of the mouth gives rise to great multiplication. They conclude that any obstruction of the mouth of the appendix is sufficient to give rise to appendicitis. [Our own experience and beliefs are in large measure confirmed by these experiments. Obstruction of the mouth of the appendix by inflammatory swelling of the mucosa of the cecum or by other causes seems to us the first step. Subsequently the microorganisms normally present multiply greatly, and occasion serious danger to the walls of the appendix.] Ramm[3] in considering the nature of appendicitis concludes that it is due to the incarceration brought about by sudden dilatation of the cecum. This causes retention of the contents of the appendix, hyperemia, epithelial desquamation, and consequent infection. He states that it is not infrequent to find an apparently healthy appendix at operations in cases in which the clinical symptoms have been those of appendicitis. Sutherland[4] believes that in many cases the pathology of appendicitis may be sketched as follows: first, the presence of constitutional poison, such as that of rheumatism, producing inflammation of the lymphoid tissue of the appendix, which is thereby so weakened that microorganisms may enter and produce a septic appendicitis or peritonitis. He urges in support of this view the fact that exposure is a potent predisposing cause, and that the early symptoms of appendicitis are frequently purely constitutional. The treatment in such cases, especially where other rheumatic manifestations exist, consists in the administration of salicylate of sodium.

Robinson[5] discusses **rheumatism** as the cause of appendicitis. He urges that there is no good reason why rheumatic inflammation should not attack the region of the appendix, and is confirmed in his belief, in the absence of pathological data, by the therapeutic test. Treatment with any form of the salicylates is sufficient, and frequent doses have, in his own experience, diminished both pain and the inflammatory manifestations in the region of the appendix more frequently than any other routine method. If an anodyne

[1] Univ. Med. Mag., Oct., 1895.

[4] Lancet, Aug. 24, 1895.
[5] Med. Rec., Sept., 1895.

is required, he prefers codein to morphin. He believes that operative treatment in such cases is bad treatment.

Frazer[1] speaks of certain forms of typhlitis that he believes are due to the **uratic diathesis,** and contends that in these cases the intestinal walls, and not the joints, are the seat of deposition. He is particularly confirmed in his opinion by the very beneficial effects in these cases of the salicylate of soda. Morphin in connection with this he believes to act beneficially in two ways: first, by increasing the acidity of the blood, and secondly, by relieving pain.

McArtney[2] reports 24 cases of appendicitis with no deaths, all of which were given purely medical treatment. All of these cases were severe and several had recurrent attacks. Abscesses developed in 4 instances, 2 opening into the bowel, 1 into the bladder, and 1 externally. He believes that if all of these cases had been operated upon at the earliest possible moment, some of them would not have survived the operation, particularly considering the unsuitable surroundings in which they were placed. He concludes that the symptoms of appendicitis are vague, particularly in cases of localized peritonitis, and that this peritonitis is not an injurious but a conservative process; and, further, that recoveries under the opium treatment are not only not exceedingly rare, but that the medical treatment is rational and more successful than is usually admitted.

Dieulafoy[3] in considering the nature and treatment of appendicitis states that **concretions and catarrhal inflammation** are the primary causes. The inflammation of the walls is always a result of local irritation. Obliteration of the lumen occurs by agglutination of the walls, and secondary bacterial invasion follows. Without perforation of the walls the microorganisms invade the tissues and local peritonitis results. Regarding the treatment, though admitting that certain cases recover spontaneously, he believes surgical operation is always indicated. Le Dentu[4] is less radical in his views than Dieulafoy. Though himself a surgeon, he insists upon operation only in cases in which certain distinct indications are present. Ephraim[5] in commenting upon Dieulafoy's paper expresses surprise at his radical views regarding operation, stating that for one who has seen hundreds of cases of recovery under the treatment with opium and rarely a fatal case this point of view seems very peculiar.

Intestinal Concretions.—Mongour[6] reports an interesting case of intestinal calculi. The patient, a woman of 31, neurotic and arthritic, had suffered with digestive disorders and dilatation of the stomach for several years. The symptoms of mucomembranous colitis developed, and there was sharp pain along the colon and obstinate constipation. For 6 or 7 months the patient passed small stones in addition to the membrane. These varied from the size of a seed to that of a nut, and their discharge occupied the period of 2 weeks.

[5] Centralbl. f. innere Med., June 20, 1896.
[6] Compt. rend. de la Soc. de Biol., Feb. 28, 1896.

They were homogeneous on section, and were composed of carbonate of calcium and phosphate of magnesia with organic matter and iron. Mongour believes that these stones are formed in the intestines in the same manner that stones are formed in the bile-passages and in the kidney.

Intestinal Infection.—Beco[1] has contributed a most interesting article bearing upon the question of infection by microorganisms from the gastro-intestinal tract. His investigation consisted in the bacteriologic examination of the spleen from ¼ to ¾ of an hour after death, and also 24 hours after death, in 25 cases. In 11 instances the bacterium coli commune was found in the spleen immediately after death; in only 4 cases it was absent, but was found 24 hours later. He explains the subsequent occurrence in these 4 cases as due to multiplication of bacteria during the 24 hours, rather than to postmortem invasion of the spleen taking place during the interval. It is of interest to note that in cases in which other microorganisms were associated with the B. coli commune at the first examination the associated microorganisms were absent at the subsequent examination. The explanation of the author is doubtless a proper one—that the B. coli multiplies at the expense of the other forms. The author also experimented upon animals by administering irritating chemicals, and found that in cases in which repeated death (within 24 hours) occurred, bacteria were absent from the blood and organs, whereas they were present when death occurred more gradually. [These investigations are of extreme interest as bearing on the liability to terminal infections in chronic diseases or in conditions in which lingering death takes place; and they will serve also to rob the Bacterium coli of the importance which has sometimes been attributed to it in connection with widespread diseases with which it has been associated.]

Nuttall and Thierfelder[2] have shown that bacteria in the intestines are unnecessary to the life of guinea-pigs, and therefore of other animals and man, at least when the diet is an animal one. They removed young animals from the mother by Cesarean section, and placed them in a specially constructed jar where they could be fed with sterilized milk and protected from any bacteria. After a week, during which they showed all signs of an active healthy condition, they were removed and examined. Bacteria were wanting in the intestines.

Herter and Smith[3] have investigated elaborately the question of intestinal putrefaction and its effects on the urine. No definite conclusion can be drawn from the amount of ether or sulphuric acid, as the amount and kind of food cause important alterations. A more certain indication is given by the relation between the total and the preformed sulphates. No definite relation exists between the aromatic sulphuric acid and the quantity of indican. The kind of the aromatic substances probably depends upon the species of bacteria causing putrefaction. The constant elimination of 5 mg. of indican in adults, or even less in children, is pathologic. The excess depends upon the increased

[1] Ann. de l'Inst. Pasteur, No. 3, 1895. [2] Zeit. f. physiol. Chemie, Bd. xxi. H. 2 and 3.
[3] N. Y. Med. Jour., June 22 to July 20, incl., 1895.

putrefaction of albumins or deficient altered activity of the bile and pancreatic secretions. In such cases flatulence occurs, and the whole condition may be benefited by change of diet. In other cases there is continuous cause of indican with or without flatulence, uninfluenced by diet. While the aromatic sulphates are probably toxic, it is likely that other substances formed at the same time are rather more important in producing the general manifestation. The quantity of hydrochloric acid in the gastric juice is of doubtful relationship. Finally, disturbances resulting from increased putrefaction were never absent when the relation of the sulphates was below 1 : 8. Among the intestinal antiseptics, salol, resorcin, and salicylate of sodium seem to have some though slight action. Hydronaphtol and betanaphtol are practically useless. Milk diet and pure albuminous or pure meat diet are efficient. Soft-boiled eggs may be employed. Overexercise and sexual excesses must be avoided.

Albu[1] has studied the question of intestinal antisepsis, and concludes that certain remedies (naphthalin, benzonaphtol, and phenolein or isobutylphenol) have some though extremely restricted power. The effect was measured by the relative proportion of aromatic and fixed sulphates in the urine, and of indol, skatol, and phenol in the intestinal excretions. The surest method of intestinal antisepsis is cleansing the bowels by laxatives or enemata and administration of sterile food. Of course the latter is almost impossible, though approximate sterilization may be obtained.

Surveyor and Harley[2] contribute experiments bearing upon the value of **bismuth subnitrate** and **betanaphtol** as intestinal antiseptics. In experiments outside the body the former substance is the more powerful when large doses are used, but internally the latter proves more efficient, since the constipating effect of the bismuth counterbalances its effects as an antiseptic.

Intestinal Anthrax.—Krumholz[3] reports a case of intestinal anthrax manifesting itself with choleraic symptoms. Both the small and large intestines contained numerous hemorrhagic elevations and generalized edema. There was swelling of the spleen, of mesenteric and retroperitoneal glands, with ascites. Anthrax bacilli were found in the blood and in the peritoneal exudate, but were particularly abundant in the lymphatics, where they seemed to have multiplied, entering the blood in comparatively small numbers.

DISEASES OF THE PERITONEUM.

Witthauer[4] reports 2 cases of **subphrenic abscess** due to perforation of gastric ulcers. In both the patients had suffered with gastric symptoms for some time, when sudden pain, weakness, and collapse developed. The cases presented no unusual features.

Robinson[5] in a study of **local peritonitis** points out that this is of

[1] Berl. klin. Woch., No. 44, 1895.
[2] Brit. Med. Jour., No. 1824, 1895.
[3] Ziegler's Beiträge z. Path. Anat., Bd. xvi. H. 2.
[4] Therap. Monats., Oct., 1895.
[5] N. Y. Med. Jour., Jan. 25, 1896.

extreme frequency, and that rarely is there entire absence of evidence of such an occurrence in some part of the peritoneum of adults. In occurs especially at the fixed flexures of the bowel, and leads to adhesions which may prove serious. In certain parts, as about the cecum and appendix or the gall-bladder, adhesions are extremely common and often innocuous. The explanation of chronic local peritonitis is infection following abrasions of the mucosa, aided by trauma due to muscular action in a bowel containing pathogenic microorganisms.

Shattuck[1] presented in clinic a case of a man who had suffered from pleural effusion, tubercular ostitis, lymphadenitis, and peritonitis. Complete recovery occurred after tapping the sacculated peritoneal effusion, and had persisted for 6 years.

Abdominal Tumors.—Pagenstecher[2] refers to **mesenteric cysts.** These may be either dermoid, chylous cysts, or productions of the caseation of mesenteric glands. He refers to 2 cases—one a chylous cyst, the other probably derived from a mesenteric gland. In 1 case movable kidney was simulated, and was suspected for a long time.

Nothnagel[3] considers the movability of abdominal tumors, calling attention to the great difficulty of diagnosis and the need of personal experience. Four elements must be considered in the question of movability: 1. The respiratory movements of the diaphragm; 2. Peristaltic movements of the stomach and intestines; 3. Pressure from without; 4. The weight of the mass. 1. Tumors of the liver, spleen, stomach, and to a certain extent of the kidneys, move with the respirations. A distinction between hepatic and gastric tumors may be possible when the tumor can be held back during expiration, this indicating the stomach as the seat. Respiratory movement of tumors is absent when the diaphragm is motionless, as in pleurisy and emphysema; also when the tumor has become adherent or when the liver and spleen are so large as to interfere with the movement of the tumor. The moderate movability of renal tumors is occasionally useful as a distinction from retroperitoneal tumors. 2. Tumors of the stomach and intestines may have movement due to peristalsis. Great movability on palpation may indicate a dislocated organ or a tumor of the intestines. This is an important point in distinguishing between a tumor of the bowel and a perityphlitic abscess. Among the fixed tumors are abscesses, sacculated exudates, aneurysms, tumors of the pancreas, of the retroperitoneal gland, of the bones, and of the undescended testicle. Movements of the tumors due to their own weight may cause considerable dislocation, particularly in tumors of the stomach.

Levi[4] reports 2 cases of hepatic disease, in 1 of which somnolence was constantly present during the early stages of a cirrhosis, and in the other intermittent narcolepsy occurred in relation to cholelithiasis.

DISEASES OF THE LIVER.

Jaundice.—Plowright[1] refers to the epidemic prevalence of catarrhal jaundice in King's Lynn during the later months of 1895. In all, 34 cases occurred in his own and in his colleagues' practice. Of these, ½ occurred in young persons—that is, under 20 years. The majority of the cases occurred in females. The degree of prevalence may be seen from the fact that but 25 cases of typhoid fever occurred in the same district. During the same time 25 of the 34 cases occurred in October and November. Malaise was sometimes present, and as often absent from the prodromal period of the disease. Vomiting was a frequent symptom. Most cases were well in 10 days; none died. [We have been struck by the frequency of mild jaundice occurring during the winter and spring months of the last several years, and have been disposed to attribute it to the prevalence of influenza. Gastrointestinal forms of this disease and intestinal complications have been more abundant than previously, and in equal measure jaundice has appeared to increase in frequency.]

Banti[2] records a case of jaundice which from the symptoms (headache, fever, chill, and absence of appetite, with swelling of liver and spleen and slight icterus) presented the appearances of an infection. Gastrointestinal symptoms, with the exception of loss of appetite, were completely wanting. The blood of the spleen extracted during life with every care to prevent contamination showed a capsulated bacillus, which resembled the bacillus of rhinoscleroma and capsulated forms of proteus and was evidently a distinct species. The author believes this to have been the specific cause of the jaundice in his case.

Neumann[3] considers the question of **jaundice in association with syphilis,** and refers to the following points as indicating a close relationship between the two conditions, rather than an accidental complication: 1. When the jaundice begins without gastric disturbances, and especially when there is simultaneously a skin-eruption; 2. When relapses of the jaundice occur with relapses of the eruption; 3. When there is tenderness over the liver or swelling of the same coincident with the eruption; 4. When the antispecific treatment causes disappearance of the jaundice; 5. When there are evidences of other syphilitic intestinal diseases coincident with icterus. The author refers briefly to 13 cases of icterus in recent syphilis, 9 of the patients being women and 4 men. In 10 there were no gastrointestinal disturbances, while in 1 there were gastric troubles in the later stages. In another the symptoms of gastrointestinal catarrh existed at the onset. The latter was enlarged in 1 case, and in another it was somewhat decreased in size. In 8 cases the jaundice appeared simultaneously with the eruption, in 3 later and 2 earlier. In 1 case the jaundice relapsed and recurred twice, with simultaneous occurrence of exanthema. In 4 of the cases the first eruption was accompanied by icterus; in 9 the latter occurred with recurrences of eruption. Antispecific treatment was

[1] Brit. Med. Jour., May 30, 1896. [2] Deutsch. med. Woch., No. 31, 1895.
[3] Wien. med. Presse, No. 45, 1895.

followed by relapse in 12 cases; 1 patient died. The latter was an instance in which the disease had existed 8 months and which had been treated by subcutaneous injections. In the later stages delirium, convulsions, and coma developed and ecchymoses were seen upon the surface. The autopsy showed parenchymatous nephritis, cystitis, and pyelitis. The liver was small, and presented on its surface elevations which on section were found to be enlarged lobules. The microscopic examination showed regeneration of the liver cells in adenomatous form secondary to degeneration of the liver.

Boisson[1] reports 3 cases of jaundice, in all of which it was impossible to find any trace of bile-pigments in the blood or urine, and in which he concludes that the coloration was due to destruction of the corpuscles in the circulation. [Stronger proof must be furnished in support of this view. Recent investigators are nearly all in accord that true hematogenous jaundice never occurs.]

Kester[2] reports the case of a boy, aged 3, who had been jaundiced for 2 years before he came under observation with chronic pneumonia of the right lung. The jaundice disappeared, but the boy died, and at autopsy the chronic pneumonia was found to be tubercular. The cause of the jaundice was discovered to be pressure of large **glands in the fissure of the liver.** The liver was about normal in size, but tubercles were scattered throughout the substance and the ducts were dilated. A perforation of the common duct was found at the lower end, communicating with a cavity containing caseous material.

Knight[3] reports a similar case of jaundice in a child of 6 years. The patient quickly recovered from a first slight attack associated with enlargement of the liver, but a month later jaundice reappeared, and the liver was still smooth and not sensitive. In a short time his eyesight became imperfect; the boy grew drowsy, and the liver diminished in size. The urine contained a trace of albumin and bile-pigment, but no leucin or tyrosin. Later he had convulsive attacks attended by screaming and pain in the back. The liver was found to be retracted, small, and pale. Microscopically, tuberculous lymphatic enlargements were found in the portal fissure. The spinal cord was not examined. [We have recently observed 2 cases of gastric carcinoma in which persistent jaundice was caused by the pressure of enlarged lymphatic glands in the fissure of the liver. Cases of this kind are not unusual. Tuberculous disease of the glands leading to jaundice, however, is less frequently observed.]

Joffroy[4] reports a case of an individual of alcoholic habits who was suddenly seized with difficulty in walking and an apoplectiform seizure. After this, general apathy and disturbance of the movements of the lips and tongue, with slow speech, developed. Fibrillary tremor of the tongue and lips was absent. The pupils were regular. Urobilin was found in the urine, and the general condition of the patient greatly improved. Subsequently a relapse occurred, and at the same time grave icterus developed and the patient died.

The hepatic nature of the affection was thus established, and general paralysis was excluded.

CIRRHOSIS.

Etiology.—Arthur Foxwell[1] calls attention to the fact that **alcoholic cirrhosis** of the liver not infrequently leads to enlargement of that organ, and points out that clinicians usually overlook this fact. In his own experience he distinguishes 4 groups of cases: in the 1st, in which ascites did not appear, and which were relieved by treatment, 26 of 28 cases presented enlargement of the liver, the edge being found on an average $2\frac{1}{4}$ in. below the ribs. Some of these were cases of long standing alcoholism. In the 2d class, in which ascites had occurred, but in which treatment had relieved the symptoms, 9 at least of 18 presented enlargement, while in several no report of the size of the organ is made. In the 3d class, which included fatal cases without postmortem examination, the edge was far below the ribs in 9 of 12, and taking the 12 cases together the liver extended on an average $2\frac{1}{4}$ in. below the ribs. In the 4th class, consisting of fatal cases where postmortem examination was made, there were 8 cases, 3 of which were women and 5 men. In the former 3 the average weight of the organ was $48\frac{2}{3}$ oz. against the normal weight of 45 oz.; in the 5 males the average weight was 64 oz. against the normal 53. Taking all the cases together, it is seen that the liver was actually far below the ribs in 46 cases, and taking all together the average extent of cirrhotic liver below the ribs was $1\frac{6}{11}$ in. His studies further showed that the enlargement did not depend upon fatty infiltration, and beer-drinking seems less likely to produce enlargement than the drinking of raw spirits.

Parker[2] records a case of extreme hepatic cirrhosis **in a boy of 12.** Diarrhea, jaundice, ascites, hematemesis, and melena were prominent symptoms. Treatment was without effect, and he died. The autopsy revealed a hob-nail liver one-third the normal size, and an enlarged spleen. There was inflammation of the cecum and colon. No cause could be discovered, but the child's father was a moderate rum-drinker for a year or two before the child's birth.

Pick[3] in an article on **pericarditic pseudocirrhosis** of the liver calls attention to enlargement of the liver with ascites, but without jaundice, as a symptom sometimes found to be due to latent pericarditis. The latter causes disturbance in the circulation of the liver, leading to connective tissue overgrowth and to intense ascites through congestion of the portal circulation. It is especially common in early life, though it occurs in old age, and is distinguishable from ordinary cirrhosis by the absence of alcoholism and similar causes, by the history of pericarditis, and the existence of primary edema of the legs.

Weber[4] reports a case of cirrhosis of the liver characterized by jaundice of 4 years' duration. At the autopsy the liver weighed 54 ounces. Its substance was tough, its surface puckered or granular, and its color greenish.

[1] Brit. Med. Jour., Feb. 15, 1896.
[2] Ibid., Feb. 22, 1896.
[3] Zeit. f. klin. Med., Bd. xxix. p. 385.
[4] Brit. Med. Jour., Apr. 25, 1896.

The common bile duct was considerably distended, and near its orifice under the duodenum were two black gall-stones, the larger one about as large as a cherry-stone. Some of the contents of the gall-bladder could be squeezed into the duodenum. The spleen was greatly enlarged. Weber inclines to the belief that cirrhosis was produced by the constant irritation of the back flow of the bile, the gall-stones in the common bile duct acting as a ball valve and preventing its escape into the duodenum.

Symptoms.—Preble[1] reports 4 cases of fatal **gastrointestinal hemorrhage** due to cirrhosis of the liver. In all of these cases there were varicose veins in the lower part of the esophagus. In the 1st case the point of rupture was not found: in the 2d and 4th a rupture was found in one of the dilated esophageal veins. In the 3d an esophageal ulcer had perforated the venous wall. Gauthier[2] calls attention to the fact that gastrointestinal hemorrhage may precede the other symptoms of cirrhosis of the liver, by a considerable period in certain cases. There may be no premonitory symptoms, while in other cases headache, depression, and symptoms resembling those of a specific fever may occur. Usually the hemorrhage is severe and sudden; it may prove fatal or it may cease, leaving no subsequent symptoms. It is especially in the atrophic form of cirrhosis that hemorrhages occur, and the author ascribes to toxic substances which act upon the nervous system and dilate the blood-vessels an important part in the etiology. Monnier[3] records a case of alcoholic cirrhosis of the liver in which a **papular eruption** becoming vesicular, and finally hemorrhagic, appeared upon the skin just before death. Cultures showed the Bacillus coli communis and a streptococcus. Oestreich[4] calls attention to the fact that the **splenic enlargement** in cirrhosis of the liver may be out of proportion to the amount of obstruction in the portal circulation. The remaining parts of this circulation may present little congestion, though the spleen is very much enlarged. His investigations showed that the spleen presented evidences of active proliferation, and he concludes that the enlargement is due to irritation by alcohol or other poisons. The thickening of the capsule occurs coincidently and is brought about in a similar manner by irritation. Kirikow,[5] in examining the **gastric functions** of 6 cases of hypertrophic cirrhosis of the liver with jaundice, found that the total acidity is generally diminished, as is also the total HCl, while free HCl is largely diminished or even absent. The digestive functions are in general much enfeebled or quite abolished. Eichberg[6] reports a case of hypertrophic cirrhosis occurring in a young woman of 20. Icterus existed for 2 years before death, and just before the fatal termination there were aphasia and slight hemiplegia, followed by delirium, stupor, and coma. The liver presented the typical appearance of biliary hypertrophic cirrhosis.

Treatment.—Klemperer[7] recommends urea as a diuretic in cases of

[1] Chicago Med. Recorder, Dec., 1895.
[2] Jour. de Méd., Mar. 10, 1896.

[6] Med. News, Apr. 11, 1896.
[7] Berl. klin. Woch., Jan. 6, 1896.

cirrhosis of the liver. He does not find early tapping so useful as has been claimed, but, on the contrary, he has seen bad results in several cases. He administers 10 g. to 15 or 20 g. in the 24 hours, and continues the treatment for 2 or 3 weeks. The unpleasant taste is obviated by drinking milk immediately after the medicine has been taken. The remedy is specially useful in the early stages while the kidneys are in good condition, and he illustrates its activity by stating the quantity of urine excreted by cases before and after administration of the remedy. Pütz[1] reports a case of ascites in which the abdomen was tapped 47 times during 4 years, and in all nearly 1200 liters of liquid, or about 7 times the weight of the patient, were removed.

Abscesses.—Lannois[2] reports a case of abscess of the liver due to **pylephlebitis** following typhoid fever. He refers to the statistics of Schultz, who found no instances among 3686 patients, with 362 fatal cases; of Romberg, who saw 1 among 677 cases, with 88 deaths; and of Dopfer, who saw 10 in 927 autopsies. He himself found this 1 in 71 autopsies. There was no cause for metastatic abscess nor any typhoid ulceration of the biliary passages or gall-bladder. The abscess was due to ascending thrombosis beginning in the intestines, and the bacillus of Eberth was found in the abscess. The complication occurred during the fourth to fifth week, and the clinical symptoms resembled those of peritonitis. Schweiger[3] reports 8 cases of abscess of the liver in addition to 10 reported last year. Among the 18 there were 16 men and 2 women, and an unusual proportion was associated with dysentery (16 of the 18). In none of the cases of dysentery did he find amebæ, but the *Megastoma entericum* was found in 2. The pus of the abscess was also free of amebæ.

Wicklein[4] records a case of abscess of the liver in which a capsulated bacillus (B. capsulatus, Pfeiffer(?)) was discovered. There were 2 abscesses in the liver and perforation into the lung, with chronic suppurative cholecystitis, perforation into the peritoneum, and peritonitis. It is likely that the bacillus entered the liver through the biliary passages. Kuhn[5] reports a case of abscess of the liver which resulted from perforation of the wall of the stomach and secondary penetration of the wall of the superior mesenteric vein by a cocoa palm fiber. This had occasioned an ascending phlebitis extending to the liver.

Acute Yellow Atrophy.—Voorhees[6] reports a case of acute yellow atrophy of the liver occurring in a farmer previously healthy. At the autopsy the liver was about one half the natural size and very soft. Two severe attacks of gonorrhea are suggested as being etiologically related to the morbid process. Richter[7] reports a case of acute yellow atrophy following syphilitic infection. For the last 14 days of life daily examinations were made of the

[1] Deutsch. med. Woch., Feb. 20, 1896.

[7] Berl. klin. Woch., No. 21, 1896.

urine to determine the amount of urea, ammonium, the alloxin bodies, and the uric acid excreted. The total quantity of nitrogen remained almost constant. The urea was perfectly normal in amount until the last 2 days, when, during the existence of severe coma, there was a moderate reduction. The ammonium was slightly increased, but hardly enough to be supposed to be the result of insufficiency of the hepatic cells and consequent imperfect formation of urea. Richter prefers to believe that it was the result of the excessive production of acids, such as might easily occur in acute yellow atrophy of the liver from degeneration of the albumin of the organs. This is the probable explanation in the present case, because the alkalinity of the blood, carefully triturated according to the method of Löwy, only equalled 212 minims of sodium hydroxid. Uric acid and the alloxins showed both a relative and absolute increase, but the amount excreted was subject to considerable daily variation. The amount of ingested nitrogen equalled about 3½ g. a day, and, as the average excreted was nearly 3 times this, it gives an indication of the amount of albumin-destruction. A second case also occurred at the clinic, and was examined for 5 days during the course of the disease, examination ceasing 3 days before death. The patient was a young woman who had acquired syphilis 6 months previously. The results were identical with those of the first case studied. Richter believes that the theory that the coma in acute yellow atrophy is due to inadequate formation of urea is necessarily false, for in the first case coma occurred before any reduction whatever in the daily excretion of urea had occurred. He further believes that we can no longer hold that urea is formed exclusively or even chiefly in the liver, or that if we do consider that it is thus formed, then we must believe that, as the liver is destroyed, the parenchyma of other organs is capable of taking on this function and adequately performing it.

Aufrecht[1] reports a case of acute atrophy of the liver occurring in sclerema neonatorum. 24 hours after birth the child presented slight swelling of the feet, which increased so that in the next 48 hours it had occupied a considerable part of the lower half of the body. The skin was hard and doughy, but pitted slightly on pressure. Cyanosis developed, and later jaundice, and in addition small punctate hemorrhages were seen in the skin. The child died, and at the autopsy the liver was found to be small, weighing 100 g. On section it presented a dark reddish bluish appearance, and the acini could not be distinguished. On microscopic examination the liver-cells showed evidence of marked degeneration (coagulation necrosis and vacuolization) and were irregularly distributed, showing no evidence of the normal columnar arrangement. Hemorrhages were abundant, and small bacilli (possibly *Bacillus coli communis*) were observed in the stained sections.

Echinococcus Cysts.—Page[2] reports a case of hydatid cysts of the liver and of numerous other organs and portions of the body. There was a right-sided empyema, multilocular cysts of the liver, cysts of the peritoneum, omentum, and mesentery, with adhesions of the intestines. The bladder con-

[1] Centralbl. f. innere Med., Mar. 14, 1896.

[2] Med. Rec., Sept. 21, 1895.

tained 6 to 8 small cysts, and in these, as in the liquid of all of the other parts, hooklets were detected. Cardarelli[1] discusses the difficulty of diagnosis between echinococcus cyst of the liver pointing upward and pleurisy with effusion. The complete absence of breath-sounds and the occurrence of pains beneath the shoulder-blade are significant points. In pleurisy the heart is pushed to the left, in hydatid cysts to the left and upward. Sometimes an elastic resistance may be felt and fluctuation occasionally occurs. He warns against exploratory aspiration excepting under the strictest precautions.

Malformations.—McPhedran[2] reports 7 cases in which a tumor was present in the right hypochondriac region; 5 of these cases occurred in women, 1 in a man, and 1 in an infant of 11 months. In 4 of the cases complications occurred, and celiotomy was performed for the purpose of exploring the mass. In every instance this was found to be an accessory lobe of the liver. The most interesting was that of the child, which had had symptoms of severe intestinal irritation which was found at the autopsy to be due to hemorrhagic pancreatitis. In this case the lobe of the liver was about the size of a finger, and extended downward on the right side.

Mester[3] reports a case of **aneurysm of the hepatic artery** occurring in a man who had been kicked in the abdomen by a horse. This had been followed by pain in the hypochondrium, intermittent jaundice, vomiting, and the passage of fresh or altered blood by the rectum. The patient died, and at autopsy a false aneurysm of the right branch of the hepatic artery was found within the liver. It communicated with one of the hepatic ducts. He has collected 19 cases from the literature, which showed that the diagnosis is never made during life, the condition being mistaken for ulcer of the duodenum (as in his case) or for gall-stones.

Gall-stone.—Hanot and Letienne[4] divide biliary calculi into microbic and nonmicrobic. The former when fresh occur in irregular raspberry-like masses, apparently constituted of numerous elementary concretions, closely resembling dried bread-crumbs, and their crystalline arrangement is not regular. Their color is usually pale. The old concretions of microbic origin resemble the descriptions of gall-stones usually given. The calculi of nonmicrobic origin are only found in cases of obstruction of the common duct due to pressure from without. They are very regular in form and show numerous indentations of their surface, containing yellow bile-pigment and contrasting with the black color of the stone itself. The microorganism concerned in the formation of microbic stones is almost invariably the bacillus coli communis.

Fenger[5] in an interesting paper upon the **surgical treatment of gall-stones** points out certain features of interest in the symptomatology and diagnosis. The pain, he finds, is seldom located in the region of the gall-bladder or in the right hypochondrium when the stone is lodged in the com-

[1] Giorn. Internaz. delle Scienze Med., Feb. 29, 1896. [2] Canad. Pract., June, 1896.
[3] Zeit. f. klin. Med., Bd. xviii. p. 93. [4] Compt. rend. de la Soc. de Biol., Dec. 27, 1895.
[5] Am. Jour. Med. Sci., Mar., 1896.

mon duct, unless coincident inflammation of the gall-bladder is present. Very frequently he finds the pain in the epigastrium, and not rarely in the back. He regards the localization of the pain away from the gall-bladder as characteristic of floating stone. Remittance of pain with sudden subsidence, attended with flow of bile and without discharge of stone, signifies a single stone or a few stones floating in the dilated common duct. Change of position causing a relief of pain is a further evidence of floating stones. Regarding biliary fever, he believes that the possibility of this being due to absorption of aseptic bile cannot be denied, and cites 1 of his cases in which the attacks of retention were always accompanied by fever, and yet the bile in the common duct was sterile. [The ball-valve action of a gall-stone in a dilated duct was described by Osler a number of years ago.]

Levi[1] calls attention to **somnolence and narcolepsy** as a result of diseases of the liver, and he reports 2 cases showing this relation. In one somnolence was constantly present during the early stages of cirrhosis of the liver. The patient was taken with attacks of sleepiness, and would sleep all day on holidays, only waking for his meals, and had difficulty keeping awake at all, often going asleep at his work. In the second case the individual suffering with hepatic colic had attacks of intense drowsiness, while between attacks of colic she was perfectly wakeful.

Moss[2] reports a case of biliary colic with the expulsion of 3 stones at intervals. As fever of tertian type had occurred, the system had been saturated with quinin, and he regarded this as an important factor in aiding the expulsion.

Pariser[3] contributes a paper on **nervous biliary colic,** 7 such cases having come under his observation in the last 3 years. He holds that it is an uncommon affection, though many cases are looked upon as instances of gall-stone, and thus make it apparently rare. Fürbringer called attention to the fact that the pain in this condition is localized to the liver, while in gall-stones it radiates to a distance. Pariser further points out that the attack is usually short, though it may last for several hours, and that vomiting and jaundice may sometimes occur at the end of the attack. The nature of the disease is hysterical or neurasthenic, and the treatment should be conducted with this nature in view.

Turnbull[4] advocates the use of **nitroglycerin** in biliary colic, and reports a case in which it produced permanent relief.

Kelynack[5] refers to the relation of gall-stones to primary cancer of the gall-bladder. He states that gall-stones occur in 6 to 10% of all cases coming to autopsy, and that the female sex is four times as liable to it as the male. Regarding the theories which have been devised in explanation of the occurrence of gall-stones in association with cancer of the gall-bladder, he holds that the view that the association is accidental cannot be maintained. It is

[1] Arch. gén. de Méd., Jan., 1896. [2] Jour. Am. Med. Assoc., Apr. 18, 1896.
[3] Centralbl. f. innere Med., Apr. 25, 1896. [4] Lancet, Feb. 6, 1896.
[5] Practitioner, Apr., 1896.

possible, on the other hand, that the tumor may furnish conditions favorable to the formation of a stone; but the author inclines more strongly to the third theory, that the gall-stones exercise a local irritation eventuating in cancer-formation. At all events, the presence of stone does favor the development of cancer in predisposed individuals.

DISEASES OF THE PANCREAS.

Thayer[1] reports a case of **acute pancreatitis** with secondary **parapancreatic abscess** and disseminated fat-necrosis. The patient, a man of 34, had been a regular drinker of beer and whiskey, and had latterly suffered with attacks of nervous dread, and for about 2 years with morning nausea, vomiting of greenish matter, and abdominal cramps. On admission to the hospital there was found a deep-seated tumor in the epigastrium, covered by tympany and not moving with respirations. The urine was free of albumin and sugar, and there was slight leukocytosis. The temperature was elevated, and the patient's general condition was one of depression and mental confusion. Operation was performed and the patient recovered. Considerable quantities of necrotic fat were discharged through the incision. The author reviews the more important literature bearing on the nature and peculiarities of fat-necrosis. Bonsdorf and Sievers[2] describe 2 cases of acute gangrenous pancreatitis in which the symptoms resembled those of acute intestinal obstruction. Areas of fat-necrosis were found in the glands of the mesentery, epiploic appendages, capsule of the kidney, and other parts. Ascitic liquid of brownish color, from admixture of altered blood, was found. Williams[3] reports a case of acute pancreatitis. The patient, after suffering with intestinal indigestion for a few days, was seized with violent abdominal cramps, which were followed by attacks of vomiting and associated with intense pain and violent frontal headache. The symptoms grew progressively worse; there were signs of heart-failure, and death occurred on the third day. At the autopsy acute pancreatitis, with degeneration of the cells and hemorrhages, was discovered. The omentum and mesentery were found discolored with spots of fat-necrosis. These areas had a homogeneous and finely granulated surface, and on examination with high power masses of needle-like crystals were found, corresponding to areas in which the fat-globules had changed into a granular substance.

Stockton and Williams[4] report 2 cases of **fat-necrosis.** The first case, a man of 59, had suffered with extreme fatigue, flatulence, and depression. The urine contained no albumin or sugar. Suddenly, after a chill followed by a hearty meal, he was seized with vomiting, retention of urine, and pain and tenderness in the abdomen. There were great thirst and slight fever. He improved slightly and returned from Europe, where he had become ill. Soon after his arrival prostration and the appearances of toxemia developed, and he died in coma a few days later. Albumin had been found in the urine

[1] Am. Jour. Med. Sci., Oct., 1895.
[2] Finska. la Karesallskapeto. Handlingar., Bd. 36, 1895.
[3] Chicago Med. Recorder, Jan., 1896.
[4] Am. Jour. Med. Sci., Sept., 1895.

once, but was subsequently absent. There was no sugar. In the second case a man of 39 was taken ill while at work with pain and nausea; fever developed and the patient was slightly jaundiced. The urine was negative, and there were great tenderness and distention of the stomach, great thirst, and occasional vomiting. Rapid death ensued. In both cases there was marked fat-necrosis in the fat of the omentum and other parts of the abdomen. The pancreas in the first was slightly if at all diseased, though the epithelium of the ducts and of the substances in places refused nuclear stains. In the second case there was round-cell infiltration, hemorrhagic exudation, and considerable increase of interstitial connective tissue.

Chronic Pancreatitis.—Riedel[1] reports 3 interesting cases of disease of the head of the pancreas, in which the condition was due to gall-stones, and the head of the pancreas was converted into a tumor of stony hardness. At the autopsy of one the condition was determined to be interstitial pancreatitis. One of the cases was at first mistaken for carcinoma, though the further history excluded cancer. In the second case the tumor was mistaken for the gall-bladder.

Harley[2] has studied the question of the absorption of various elements of the food in a case of **obstruction of the pancreatic duct,** and in dogs in which partial pancreatic extirpation had been practised. The patient referred to was a boy, who discharged fatty stools, and in whom the diagnosis of obstruction of the pancreatic duct could be made with considerable probability. The author found that only 26.29% of the fat of the ingested milk was absorbed and 60% of the nitrogen. These results correspond very accurately with those obtained in dogs, and in which a large part of the pancreas was removed by operation. It was noteworthy that in his experiments and in the patient the splitting up of fats occurred in the intestines.

Carcinoma.—Fothergill[3] reports a case of cancer of the head of the pancreas. There was absence of fatty stools, of jaundice, and of digestive disturbances. The positive symptoms were rapid emaciation, deep-seated pain and tenderness, and glycosuria. The tumor was found in the umbilical rather than the epigastric region.

Cochez[4] has studied the hepatic manifestations in cancer of the head of the pancreas, and calls attention to the fact that, despite chronic and progressive jaundice, the liver may not be enlarged and the gall-ducts may not be dilated. In this form of mechanical biliary cirrhosis of the liver the organ is first enlarged and subsequently contracted. When the gall-bladder is not obstructed, it acts as a reservoir, and a slow progress of the case with development of the atrophic stage is observed. When the gall-bladder is obstructed, the more rapid form appears and death in the hypertrophic stage of malignant jaundice occurs. [In the cases under our observation it has not been possible to establish sharply defined stages of hypertrophy and atrophy. Practically, all cases have been marked by enlargement of the liver.]

DISORDERS OF THE URINARY SECRETION AND DISEASES OF THE KIDNEYS.

Disorders of the Urine.—Linossier[1] has carefully investigated the **digestive alkalinity** of the urine. He believes that to a certain extent it depends upon the amount of hydrochloric acid secreted by the stomach—that the secretion of the bile tends to diminish it, but that there are such a number of subsidiary factors acting that it is of no value as a symptom excepting when it can be determined that the biliary secretion is normal. If, then, the digestive alkalinity of the urine fails, it may be suspected that there is a hyperacidity of the stomach.

Mathieu and Tréheux[2] have investigated a number of cases to determine the relation between the **acidity of the stomach-secretion and of the urine,** and have found a rather close dependence of the latter upon the former. The greater the amount of acidity in the stomach as the result of hypersecretion of HCl or of fermentation and production of lactic or other acids, the greater the acidity of the urine. In some cases the natural reduction of acidity or alkalinity that succeeds a meal may be largely counterbalanced by the acid production within the stomach.

Armstrong[3] reports the case of a man of 74 who was admitted to the hospital suffering with **suppression of urine** for 8 days. Some twitching developed, and later rambling, dimness of vision, and inability to recognize his friends. These symptoms disappeared promptly with restoration of the secretion; 18 days later another attack occurred and proved fatal. Postmortem, carcinoma of the left kidney and ureter and a separate focus completely blocking the right ureter were found. Rininger[4] reports a case in which suppression of urine existed for 48 days in a girl of 18. The appetite and general condition remained good, excepting some sensitiveness in the renal region. Recovery followed faradization of the regions of the kidneys. [The author does not consider the existence of hysterical simulation in discussing the case.]

Roberts[5] records a case which presented severe lumbar pains extending into the thighs, depression and languor, with loss of flesh. There were constipation, pain on micturition, and a voracious appetite. The only evidence of disease was extreme phosphaturia. The patient recovered completely upon acid treatment.

Dupray, Cazin, and Savoire[6] have studied 15 cases of carcinoma to determine the value of **Rommelaere's sign.** According to this, diminution of the normal NP_2O_5 and NaCl is pathognomonic. The authors find that the test is an indication cachexia, but that with suitable nourishment it disappears.

Eichhorst[7] reports the case of a boy of 10 years who suffered with urinary symptoms during an attack of cholera morbus, and finally passed large numbers

[7] Deutsch. med. Woch., No. 4818, 1896.

of small round or elongated **calculi** composed of **uric acid,** together with bloody urine. He points out that disturbances of the stomach and intestines are prone, in children, to lead to increased uric-acid secretions. Cases, however, in which actual calculi have occurred have not been described.

V. Noorden [1] contributes a most interesting paper on the **treatment of uric-acid concretions** in the kidneys. Four indications are presented: 1. The administration of considerable liquid; 2. The use of a diet which shall produce uric acid in a minimum amount; 3. The administration of substances which will render the urine more solvent to uric acid; 4. The avoidance of substances which reduce the solvent power of the urine. Regarding the diet, the author holds that in actual practice it is scarcely possible to carry out a plan which will bring about the desired results. To fulfill the third indication, sodium and lithium salts, urea, piperazin, and other substances may be used; and for the fourth point he advises care in the use of strong mineral acids. Particularizing upon the alkaline treatment, he holds that it is difficult to maintain an alkaline reaction of the urine for any length of time, and that it is sufficient to procure a moderately weak acid reaction. This removes the monophosphate of sodium, which in particular renders the urine insolvent, while the biphosphate of sodium remains and is actively solvent. Finally, the author recommends the administration of carbonate of calcium or the vegetable salts of calcium instead of sodium and lithium salts. This treatment causes the removal of phosphates through the intestines, and thus relieves the urine. He has used this treatment in 21 cases with excellent results. There were only 2 attacks in the 9 months during which the treatment was used among these cases, whereas some of the cases had been having attacks every few weeks. He uses from 2 to 4 g. of calcium carbonate a day, but in some cases as much as 10 g. is necessary to remove the monophosphate of sodium from the urine. Smaller quantities of the soluble vegetable salts suffice.

De Dominicis [2] discusses the subject of **oxaluria** thoroughly. According to him, the most frequent symptoms are constipation and dyspepsia; besides these there occur palpitation, irritation, malaise, hypochondria, or melancholy disposition, loss of self-confidence, impotence, easily acquired fatigue, apathy, anxiety, and perhaps suicidal tendencies; with these are associated progressive emaciation, and sometimes changes in the skin, such as eczema, loss of hair, and frequently there are hemorrhages from the intestines, kidneys, or lungs. Experimentally, he produces oxaluria in dogs by extirpation of the thyroid gland. Clinically, he finds it is associated with functional disturbances of the stomach, varying with the various phases of the disease. An exclusive diet of meat causes it to disappear completely. Severe functional disturbances of the stomach, however, as they occur in influenza, rarely cause oxaluria. He considers oxaluria as a symptom of the same value as glycosuria and having many analogies with the latter. The disease which has been described under the head of oxaluria is practically the modern neurasthenia. He holds that the cause is probably the action of some toxin.

[1] Centralbl. f. innere Med., Apr. 25, 1896. [2] Wien. med. Woch., Apr. 25, 1896.

Kisch[1] speaks of the necessity of an exact quantitative determination of the oxalic acid excreted with the urine. He reports 7 cases out of 34 examined in which the quantity of oxalic acid exceeded 20 mg. per liter, and was therefore considered pathologic. In all these cases the specific gravity of the urine was very high, ranging from 1026 to 1041. In 5 of the cases the amount of indican was increased, and in 3 sugar was present. In all there was considerable disturbance in the functions of the digestive organs, particularly habitual constipation. In 4 of the cases there was extreme excitability of the nervous system. He considers oxaluria as a symptom of various alterations of tissue-metamorphosis, particularly associated with disturbances of the nervous system and the organs of digestion. The systematic use of alkaline, saline, and mineral waters produced diminution of the oxalic acid in the urine.

Pfeiffer[2] speaks in high terms of the value of **Cantani's diet in oxaluria.** He reports 2 cases in which extraordinary reduction in the amount of oxalic acid took place after its employment. He also reports 6 cases which were treated with baths according to the Wiesbaden method. All these cases showed a very marked diminution of the total secretion of oxalates, although in 1 case this diminution was only evident 3 weeks after cessation of the cure. The effect of the treatment seems to last for a considerable time, 1 case having been examined 3 years after the cure and found normal.

Neumann[3] found in a case of cardiac disease in which diuretin was beginning to produce increase of the urine that sugar occurred in the latter. He refers to the recent discovery of Jacoby that **glycosuria** occurs in the urine in certain kidney-affections when diuretics have begun to act.

Rosenfeld[4] has studied the occurrence and significance of **acetone** and **diacetic acid** in the urine. Physiologic acetonuria occurs in healthy individuals who are fasting, or in small quantities even when taking a mixed diet. Slight increase of the albuminous food increases the acetone, while large quantities do not markedly increase it. Marked acetonuria from an excessive meat diet can be made to disappear after one or two carbohydrate meals, as can also that produced by fasting, the acetone being better oxidized. It would appear that acetonuria is the result of moderate albuminous decomposition, and the indispensable condition is the abeyance of carbohydrate metabolism. In diabetes acetonuria appears after the beginning of a proteid diet or a mixed diet, and is accompanied by diacetic acid. If the diabetic excrete acetone in large amounts while carbohydrate food is supplied, it is pathological. Two clinical facts are that diabetic coma never occurs without acetonuria, and that after the commencement of a proteid diet acetonuria on the one hand and coma on the other may occur. Reduction of acetone may be secured by carbohydrate feeding, by excessive proteid food, and by hunger. In a very ill case the smallest amount of albuminous matters and a rich carbohydrate supply form a most practical

[1] Centralbl. f. d. Krankh. d. Harn u. Sex.-Org., vol. vii. Heft 4.
[2] Ibid., vol. vi. Heft 6.
[3] Arch. f. exper. Path. und Pharmacol., Bd. 36, H. 1, 2.
[4] Centralbl. f. innere Med., Dec. 21, 1895.

diet. Giving glycerol, levulose, and cane sugar, with albuminous food, a relatively small amount of acetone was obtained, and he has been able to reduce acetone from 7½ to 2 g. Twice he has been able to avert commencing coma.

Hirschfeld[1] again reviews the subject of **acetonuria,** referring particularly to his previous papers, published in 1893 and last year. He showed that the addition to the diet of small quantities of carbohydrates suffices to check the excretion of acetone, though the latter had been abundantly present when the diet was purely albuminous. This is not due to any conservative influence of the carbohydrates leading to a lessened destruction of albumin, since appropriate quantities of fat serve the same purpose of preservation of albumins, and yet do not check the developments of acetonuria. The author concludes that acetonuria is closely related in some way with the metabolism of carbohydrates. Regarding the significance of the condition, he holds that pathologic acetonuria occurs only in diabetes. In this disease, despite rich carbohydrate diet, the excretion of acetone continues, sometimes amounting to considerably over 1 g. in 24 hours, whereas in health there is never more than about 0.9 g. Palma[2] has investigated the excretion of acetone and its relation to albuminous metabolism. He found that in every case of acetonuria excessive consumption of albumin could be determined, but there is no fixed quantitative relationship.

Freund[3] supports the view recently revived by Semmola, that **albuminuria** in Bright's disease results from **alterations of the blood** itself. He found that the relation of serumalbumin to serumglobulin was as 1 to 2 or 3 in Bright's disease, instead of as 1 to 1.5 as it occurs in health. In other diseases, and especially in congestion of the kidney, the relation was normal. In 1 case of pernicious anemia, however, the same excess of globulin was discovered. In studying coagulation of the blood-serum in Bright's disease he found that a temperature of 76° C. was necessary, instead of one of 70° or 74°, and the clot was never firm. Finally, he showed that the albumin of the serum in nephritis is abnormally capable of dialysis. In 15 of 17 cases the liquid which had passed through the dialyzer contained from 0.006 to 0.025% of albumin, while in other diseases none, or at least only the merest traces, pass through. [These views of Semmola and Freund are attractive, but want further confirmation.]

Marie[4] reports a case of **cyclic albuminuria** and discusses the subject. He defines the disease as a form of albuminuria occurring in apparently healthy persons, intermittent in its course and subject to certain conditions. It must be distinguished from transitory albuminuria, which may occur in healthy persons at times. The cardinal condition is that albumin is present only when the upright position is assumed, and vanishes on lying or sitting down, even though hard work is done in this position. The quantity is always small, and its composition varies in different cases and at different times. Nucleo-albumin, serum albumin, pepton, propepton, etc. have been

[1] Centralbl. f. innere Med., June, 1896.
[2] Zeit. f. Heilk., Bd. xvi. p. 463.
[3] Wien. klin. Rund., No. 4, 1895.
[4] Sem. méd., Feb. 5, 1896.

found. The quantity of urine is not much affected. As to the nature of the condition, the author believes it a special disease, probably due to perverted function of the sympathetic nerves. He does not believe it is dependent upon a minimal organic lesion of the kidney. Casts may be found, but these do not necessarily indicate renal disease.

Prestiqs[1] reports an interesting case of **albuminuria** which was observed for 7 years in a patient otherwise in excellent health. Careful physical examination showed all the organs to be normal and functionally active. The urine varied in quantity, but in general was rather above the normal amount. The urea reached 48 g. a day. The other constituents were normal in quantity. Albumin, however, was invariably present, the lowest quantity being 1 g. in a day, and the highest 5.60 g. Usually the amount varied between 4 and 5 g. and corresponded to the quantity of urine, but the proportion was not always maintained. It is particularly noted that the heart showed no alteration in its action, and that there was never any edema.

Matthes[2] has studied the urine of a case of osteomalacia and found a substance which he believes to be **nucleoalbumin,** the albumin of which has been partly hydrated. He gives to this substance the name of **nucleoalbumose.** The nature of this substance seems to be the same as that found in 4 other cases recorded in literature in which primary albumoses were reported to have been found. His own case agrees also with these in the general symptoms and in the fact that they were instances of multiple myeloma manifesting itself with the clinical appearance of osteomalacia and affecting the pelvis and thorax particularly.

Krehl and Matthes[3] contribute an interesting paper on **albumosuria.** Their investigations bear particularly upon the occurrence of albumoses in the urine in fever. On account of the difficulty of removing coagulable albumin without precipitating some of the protoalbumoses, they selected specimens in which coagulable albumin was absent. In the majority of cases of fever examined hydrated albumoses were detected, while in the afebrile cases they were absent. The reaction ceased with the decline of the fever. This was seen in scarlatina, diphtheria, influenza, and mumps. In pneumonia and typhoid fever reaction was found as well at the height of the disease as during defervescence. Examination determined that these albumoses were forms of advanced hydration, and therefore belong to the group of deutroalbumoses. They obtained these substances by precipitating with alcohol, and, injecting the dissolved precipitate into animals, found that fever lasting for a period of several days and amounting to from 1° to 2° C. was produced. Injecting a similar precipitate from the urine of normal persons, there was no elevation of temperature when the quantity of urine was 250 to 500 c.cm., and but a moderate elevation, lasting a short time, when the quantity was 2500 c.cm. They conclude that in the course of the fever of whatever nature the urine contains advanced forms of albumoses capable of producing fever when intro-

[1] Jour. Méd. de Paris, Mar. 15, 1896. [2] Centralbl. f. innere Med., Apr. 25, 1896.
[3] Deutsch. Arch. f. klin. Med., July 18, 1895.

duced into guinea-pigs. Besides these deuteroalbumoses they found a second substance belonging to the group of histons. Harris[1] contributes a paper on albumosuria. He considers carefully and at some length the recent literature bearing upon the nature of the proteid substances found in the urine, and particularly upon the distinctions of the albumoses from the peptones in the sense of Kühne. The author has studied the urine in a great variety of diseases by the method described, and has found albumoses or allied products in various suppurative conditions, and in pneumonia, influenza, phthisis, diphtheria, typhoid fever, syphilis, and 1 case of septicemia of unknown origin. Finally, the author states the following conclusions: that the term albumosuria should be substituted for peptonuria; that the albumoses are produced by the peptonizing action of microbes on the albumins of the body, these albumoses being produced in quantities in excess of what is necessary for the growth of the microbes. The albumoses being readily diffusible, the excess is absorbed by the blood and eliminated by the kidneys; finally, albumosuria is simply an indication of an infective condition.

Blumenthal[2] contributes studies of several case of **pentosuria** conducted under the direction of Salkowski. The first case, a man of 36, had applied for life insurance, but was refused on the discovery that the urine reduced Fehling's solution. Subsequently it was discovered that the reducing substance resembling glucose was absent, and that the urine did not undergo fermentation. During the subsequent 5 months repeated examinations were made and pentose was constantly present. The author has discovered the same reducing agent in other cases recorded as diabetes. Pentosuria is independent of the carbohydrates, of the diet, and, as far as is known at the present time, constitutes a disturbance of metabolism without serious significance.

Engel[3] has investigated the question of **bacteriuria** very elaborately. He finds that it is practically impossible to find a specimen of urine free of bacteria. In nephritis he has found a great variety of organisms, but he calls attention in particular to one which he found in 17 of 31 cases, and which he inclines to regard as the specific cause of some cases of nephritis. This is a micrococcus of characteristic growth and properties, having only moderate virulence, but capable of causing lesions of the kidneys when injected into animals. This organism was found in cases of nephritis of mild character, and the author believes it probably the cause of many cases beginning as mild forms of bacterial albuminuria. Regarding the manner in which bacteria produce their effects, the author holds that it is by poisonous products of metabolism produced *in loco*.

Vacquez and Marcano[4] have investigated the condition of the blood in so-called **idiopathic hemoglobinuria.** The cases under their observation was the paroxysmal form, occurring in a young man in whom the only possible cause was malaria, from which he had suffered some years previously. He was entirely free of this at the time he came under observation, and no

[1] Am. Jour. Med. Sci., May, 1896.
[2] Berl. klin. Woch., July 1, 1895.
[3] Deutsch. Arch. f. klin. Med., Bd. lvi. Nos. 1 and 2.
[4] Arch. de Méd. exper., Jan., 1896.

organic disease could be determined, although the urine contained a small amount of serumalbumin. An examination of the blood was made before, during, and after the paroxysm. It was found that 6 hours after the attack the red corpuscles diminished 400,000 per c.mm., 24 hours later 1,000,000 per c.mm. The diminution of hemoglobin was not proportionate with the diminution in the red corpuscles, but was considerably greater than would have been expected, and the regeneration of the hemoglobin was not as rapid as that of the red corpuscles. They found the alterations in the erythrocytes which Hayem has described—namely, the appearance of certain corpuscles as if they were losing their color gradually. These authors state that hemoglobinuria is rather poor, but generally accompanied by general destruction of red corpuscles during the attack. The loss of hemoglobin greatly surpasses that of the red corpuscles, as in 1 case the hemoglobin decreased $\frac{1}{3}$, while the loss of red corpuscles decreased by $\frac{1}{9}$ of the normal number. They hold that paroxysmal hemoglobinuria is a symptom and not a specific affection, and that it is necessary in every case to study the blood in order that different varieties of the disease may be distinguished.

NEPHRITIS.

Etiology.—Dessy[1] reports a case of nephritis due to the **staphylococcus pyogenes albus.** The patient died of an intercurrent attack of measles. The examination of the blood as well as the urine removed with aseptic precautions showed staphylococci repeatedly during life, and after death as well. Postmortem the kidneys showed evidences of old sclerotic changes of the glomeruli with amyloid disease of the blood-vessels. In addition to this there was acute leukocytic infiltration. The portal of entrance of the microorganism was not discovered. [It is quite likely that very many different forms of microorganisms are capable of causing nephritis. In septic diseases staphylococci and streptococci have been frequently discovered.]

Bruhns[2] records 7 cases in which marked acute **nephritis followed eczema.** The suspicion that drugs used for the eczema caused the nephritis was considered, and it is asserted that in several instances this could be entirely excluded, while in others it was quite probable that the drugs were not concerned in the development of the disease. The urine contained blood, albumin, and epithelial, hyalin, and granular casts.

Von Wunscheim[3] has investigated the **etiology of suppurative nephritis,** examining 24 cases, of which 16 were instances of ascending infection, the other 8 cases of hematogenous infection. In the latter cases staphylococci were found 3 times, the diplococcus pneumonia in 1, and the bacillus of typhoid fever in 2. Of the 16 cases of ascending nephritis, 4 were complicated with pyemia, and in these staphylococci were discovered in 3 and streptococci in 1. In the 12 cases of uncomplicated ascending nephritis the bacillus coli communis alone was found. [The frequent discovery by the author and by others before

[1] Lo Sperimentale, Aug., 1895. [2] Berl. klin. Woch., July 15, 1896.
[3] Zeit. f. Heilk., Bd. xv.

him of the bacillus coli in ascending infections of the urinary tract establish this as the most frequent microorganismal cause of such infections.]

Holz[1] reports 6 cases of acute **hemorrhagic nephritis** occurring in young persons after falls, but without injury to the spine; 2 of these cases were fatal, and died during the continuance of the symptoms; 4 recovered. In the latter the disease of the kidney did not apparently affect the general health, and in a few days the symptoms disappeared entirely. The author excludes injury of the central nervous system, from the fact that there was no injury of the skull or spine. In the 2 fatal cases small hemorrhagic areas were found in the substance of the kidney, but microscopically, in addition to the minute points of hemorrhage scattered throughout the organ, there were distinct parenchymatous changes. Holz looks upon this condition as one of a similar nature with that known as commotio cerebri.

Symptoms.—Bonnier[2] calls attention to the fact that it has long been recognized that **cramps** may be associated with Bright's disease, and suggests that some of the instances of professional cramps may be dependent upon nephritis. He details a case occurring in a telegrapher who developed an occupation-cramp following an attack of small-pox, and had also symptoms of nephritis. All treatment was unavailing until the patient was placed on a milk diet after the Bright's disease was recognized.

Pye Smith[3] calls attention to the forms of **skin-affections** which occur in Bright's disease. Among these are bright red papules similar to those caused by sweating, large discrete papules seated on a dry and sometimes scaly skin, moist dermatitis affecting the legs and arms, but not the flexures of the joints and not attended with irritation, and lastly extensive dermatitis resembling exfoliative dermatitis. All of these forms are superficial and very late in the disease. They bear no direct relation to the progress or the course or severity of the affection.

Pick[4] reports a case of **sudden amaurosis** subsiding after 24 hours, and being followed by left-sided hemianopsia, in a patient suffering with chronic nephritis. At the autopsy a spot of softening was found in the right occipital lobe. No cause for this softening was found, and the author inclines to regard it as the result of toxic influence upon the vasomotor system of the brain or upon the blood itself, causing coagulation in the vessels and consequent necrosis. The amaurosis and hemianopsia found in uremia he looks upon as results of toxic action on the central optic apparatus.

Uremia.—Ajello and Paraveandalo[5] conclude from their experiments on animals that uremia is due to the absence of the normal internal renal secretion. Animals in which one kidney was removed suffered with albuminuria and cachexia after a certain time, while animals treated in a similar manner, but receiving injections of renal extracts after the operation, did not suffer albuminuria or cachexia.

[3] Brit. Med. Jour., Nov., 1890. [4] Deutsch. Arch. f. klin. Med., Bd. lvi. H. 1 and 2.
[5] Lo Sperimentale, an. xlix. fasc. 4.

Stengel[1] considers the occurrence of **fever** in Bright's disease, and particularly in the uremic state. Fever may be associated with the onset of acute nephritis, and at this stage is ascribable either to the degenerative and inflammatory lesions of the kidney, to retention of toxic substances, or to the original infective or toxic cause of the disease. In a second group of cases elevation of the temperature is due to inflammatory complications, such as pleuritis or pericarditis. The degree of fever in such cases is inconsiderable, especially when compared with that occasioned by the same complications occurring in rheumatism. Finally, there are cases of **febrile uremia.** These may be sudden and intense and associated or unassociated with convulsions. It is specially to be noted that the temperature frequently rises before convulsions begin. A second form of febrile uremia resembles slow infectious processes in its manifestations, and particularly the typhoid state. To this the name "slow uremic fever" might be applied. A number of cases are introduced in illustration of the various types.

Rendu[2] has reported a case of **uremic aphasia** in a man of 56 who had been suddenly seized with an apoplectic attack. The morning following he had regained consciousness, and presented only aphasia, monoplegia of the right arm, and a systolic murmur at the base of the heart. Subsequently, clear evidences of uremia were obtained and the patient was bled. The monoplegia and aphasia entirely disappeared. The author concluded that the symptoms were due to uremic intoxication, and in the discussion Hanot expressed the same view regarding the similar attacks occurring in pneumonia and other infectious diseases, while Duflocq mentioned a case of aphasia occurring in cholera in which the autopsy showed no lesion.

Diagnosis.—Reinecke[3] undertook a series of experiments to determine if it were possible to decide as to the presence of nephritis when leukocytes were in the urine in considerable quantities. In a case of acute cystitis they found that the amount of albumin bore a close relation to the number of leukocytes, varying as they varied and disappearing as they disappeared. Accepting the proportion of 1% of albumin by volume (Erbach) as equal to 100,000 leukocytes in a cubic cm., the amount of albumin was considerably in excess; nevertheless, as there were no evidences of nephritis, they concluded that it was due to the leukocytes. In a case of pyelitis the curves were closely parallel and nephritis was excluded. In 1 curious case it was estimated that 57 billion leukocytes were excreted in 24 hours—a number that very considerably exceeds that of the white cells normally present in the blood. He concludes that estimations of the pus-cells frequently fail to give the exact measure of the amount of pus excreted, but that nevertheless the regular daily count gives a good idea of the course of the case and indicates the effect of therapeutic measures, and that, in connection with the differences of the quantity of albumin, it frequently serves to decide the question as to whether nephritis is present or not.

[1] Am. Jour. Med. Sci., Nov., 1895. [2] Gaz. méd. de Paris, Apr. 4, 1896.
[3] Berl. klin. Woch., Sept. 9, 1895.

Eisenschnitz[1] records the case of a girl of 16 who was treated for nephritis with universal edema and ascites. The abdomen was tapped twice, and the fluid contained 0.15% of albumin, .2% of sugar, and traces of fat. No fat-droplets were visible microscopically. Death occurred from uremia, and post-mortem a thrombus was found in the innominate vein at the point of entrance of the thoracic duct. The thrombus was movable, and the author believes the lack of chylous ascites was due to the valve-like closure of the orifice by the thrombus.

Treatment.—Friedrich[2] employed **urea as a diuretic** in 2 cases—1 of interstitial nephritis and 1 of hepatic cirrhosis—in both cases with markedly beneficial effect.

Klug[3] reports excellent results from **phlebotomy** in a case of acute hemorrhagic nephritis. There was no evidence of anemia, but considerable hematuria and edema, both of which were greatly benefited.

Huchard[4] reports a case of albuminuria and uremia occurring after the application of a **blister.** De Cresantiques[5] has observed 2 cases in which death occurred after the application of a blister. He warns against the use of cantharidal vesication in febrile diseases, because of the irritation of the kidneys already present due to the elimination of toxins.

Tyson[6] reports 2 cases of nephritis in which **salol** was given for diarrhea, and in which there was great reduction in the quantity of urine. In 1 case complete suppression of urine with a fatal issue occurred. The doses given were 5 gr., in 1 case 2 doses having been taken, and in the other but 1. [It is not improbable that the sudden control of the diarrhea by the bismuth and salol administered may have had an effect quite aside from the supposed direct effect of the salol.]

Pyelitis.—Ingria[7] reports a case of **calculous pyelitis** with atrophy of the opposite kidney in consequence of previous calculous pyelitis. The remarkable feature in the case was the fact that total anuria lasted for 8 days. No tumor developed in the region of the kidney, but on the 6th or 7th day edema of the eyelids and somnolence developed, and the breath of the patient had a urinous odor. A small concretion was discharged and the secretion of urine at once reestablished. The patient lived 4 years after this attack.

Eichhorst[8] reports the case of his son who acquired severe cholera morbus at a summer resort. On the 4th day there was burning pain at the end of urination, which soon became more severe with strangury. On the following day the urine contained a number of small lenticular reddish-yellow calculi, from the size of a poppyseed to that of half a pea, also some blood-clots and large numbers of uric-acid crystals.

Tuberculosis.—Mendelssohn[9] reported a case of calculous pyelitis

which was regarded as tuberculous and the kidney removed. In the discussion Leyden called attention to the fact that the discovery of bacilli having the features of tubercle bacilli must not be at once regarded as distinctive, as smegma bacilli are found in almost every specimen of urine, more often in women than in men. The behavior of these toward stains is much the same as is that of tubercle bacilli. He calls attention to the granular particles that occur in the urine in tuberculosis and to the coincident affection of the epididymis and prostate often observed. Gerhardt, Senator, and Fränkel agree with Leyden's view, but the latter points out that if the original Ehrlich method of staining is employed, the tubercle bacilli alone remain colored, and that the smegma bacilli do not occur in peculiar curved chains or groups like tubercle bacilli. Casper held that the use of alcohol containing HCl would discolor the smegma bacilli and not the tubercle bacilli. Hamill[1] records the case of a child that at the age of 7 months became feverish and restless, and had diarrhea with offensive stools. There was high temperature, and subsequently nervous symptoms developed. At death the right kidney was found to be several times the size of the normal kidney, being about 5 in. in length and $2\frac{3}{4}$ in breadth. The surface was irregularly nodulated, and it was found to consist apparently of a mass of various sized **tubercular nodules.** He makes a careful study of primary renal tuberculosis, and finds that the general causes are those of tuberculosis elsewhere, but that it is particularly apt to occur in males in early adult life. Usually the condition is unilateral, but if bilateral it is more pronounced on one side. It is probable that infection is usually from the blood, and he considers the possibility of the entrance of tubercle bacilli into the circulation without development of local lesions at the portal of entrance, urging in support of this view the frequency of tuberculous disease of the mesenteric glands without the occurrence of intestinal lesions. Perineal and pelvic abscesses frequently occur as complications, and the disease sooner or later involves the ureter, and even produces some changes in the wall of the bladder. The symptoms are pain, hematuria, and, in the late stage, constitutional disturbances. Of the 55 cases he finds in literature, tumor was observed in 23. The most important symptom is the discovery of the bacilli in the urine. In the 17 cases that he has collected upon which operations were performed, nephrotomy was done 4 times, with 2 recoveries, 1 improvement, and 1 death; nephrectomy was done 9 times, with 5 recoveries, 1 improvement, and 3 deaths from the operation. Nephrotomy followed by nephrectomy was resorted to in 4 cases; 2 recovered, 1 died, and 1 improved. As these operations were all undertaken upon advanced cases, Hamill argues that the results will probably be much better if the resection of the kidney is performed when the disease is absolutely localized and before softening has begun; that is, in the earlier stages.

Tumors.—Short[2] records a case that was characterized by severe pain across the loins and pyuria. The pain was intense, always becoming worse at night. Cachexia supervened, and the pain seemed to settle in the right

[1] Internat. Med. Mag., Jan., 1896. [2] Birmingh. Med. Rev., Mar., 1896.

sacral iliac joint, but later returned to the lumbar region. At the autopsy a large semisolid growth was found which occupied the left side of the abdominal cavity and appeared to surround a part of the left kidney. From gross appearance it was supposed to be carcinoma. McWeeney[1] reports 2 cases of tumors of the kidneys derived from the growth of **suprarenal "rests."** Both of his cases were women, their ages being 53 and 38 respectively, and both cases involved the left kidney. One recovered after the operation, being alive 3½ years after the removal.

ANIMAL PARASITES.

Protozoa.—Dock[2] reports a case of **trichomonas** in the urine. The patient, a student of 27, had had malarial fever, and consequently suffered with frequent urination, which was usually painful and bloody. There was no history of venereal disease. The urine when passed was pale yellow, clear, and contained a number of small whitish flakes about the size of pinheads, and some clear mucus. In these flakes were found peculiar flagellated parasites resembling very closely the Trichomonas vaginale of Donné. They varied from 15 to 25 mm. in length and from 7 to 15 mm. in width. Most commonly they were pyriform in shape, with one end rounded. The nucleus was always in the clear part, usually lying somewhat obliquely. Dock agrees with Künstler that the normal number of flagellæ is 4, but it is very difficult to see them all, the maximum number usually observed being 3. When only 3 are seen 1 flagella is thicker than the others, but this is not the case when all 4 are apparent. The posterior end of the body is sometimes prolonged into a long taillike process, and this tail appears to be due to the formation of a soft, thin, adhesive pseudopod, by which the parasite attaches itself to the cover-glass or other object. Occasionally 2 parasites are attached by the tails, which has given rise to the supposition of transverse division. Curiously enough, if 1 parasite in a preparation be found with a tail, nearly all the others possess it, and, when this organ is lacking in 1, it is lacking in all. A shallow depression or cleft near the insertion of the flagella probably serves as a mouth. Physiologically, these organisms may throw out pseudopods that are capable of a kind of oscillatory or jerking motion. They are very susceptible to cold; quinin kills them in about an hour, causing them to fill up with large clear vesicles, and salicylic and boric acids have the same effect. It was impossible to cultivate these organisms in the bladders of any of the lower animals. Reproduction is usually by longitudinal division, but there is probably some other mode which resembles sporulation. In conclusion, the author states that he cannot consider the trichomonas a harmless parasite, and that it is probably not as rare as the few reported cases seem to indicate. (See also *Dysentery* and *Diseases of the Lungs.*)

Vermes.—Moosbrugger[3] details the history of 3 cases of **trichocephaliasis** occurring in children, in whom severe symptoms were noted. Occa-

[1] Brit. Med. Jour., Feb. 8, 1896. [2] Am. Jour. Med. Sci., Jan., 1896.
[3] Münch. med. Woch., 1895, p. 1097.

sional bloody diarrhea and prostration were the symptoms observed. One of the children, aged 3 years, died of intercurrent croup, and at autopsy many worms, partly in clusters and partly free, were discovered. Ulcers and cicatrices were observed in the colon. No cases of such severity have been previously recorded.

Askanazy[1] has investigated the Trichocephalus dispar, and concludes from the fact that ferruginous pigment is always found in the epithelium of the intestinal tract that the worm lives upon blood it abstracts from the vessels of the mucous membrane of the intestine.

Ogilvie[2] refers to a previous paper published in 1894, and again insists upon the points contained therein—viz. that a preparatory treatment of considerable duration is necessary before the administration of remedies for **tapeworm,** and that the doses of the latter (filix-mas) should be considerable. He reports 1 case in a girl of 7 in which small doses had been used and had caused toxic effects, and in which he subsequently gave large doses (1 dram at 8 A. M., and 45 minims after an hour). There were no toxic effects, and the worm was removed entire. He holds that the smaller doses are retained in the bowel and to some extent absorbed, while the larger doses are discharged, sometimes within 2 hours, and frequently before the final dose of castor oil has been administered. Regarding the preparatory treatment, he advises saline aperients to be taken for a week, so as to rid the bowel of excessive mucus and expose the parasite to the full action of the poison. The vermifuge is given in 2 doses, as indicated, before and after the administration of the latter. Castor oil with jalap is used as a rapid purge.

Sommer[3] has collected all the recorded cases of **echinococcus disease** in the United States. He finds 67 cases in man, of which 17 were foreigners and 4 negroes: 24 of these cases occurred in New York State.

Garceau[4] records the case of a German who ate a small quantity of raw smoked ham. For 2 weeks he felt rather miserable, and then began to have some fever. The muscles began to feel sore, and there were a few red spots on the abdomen, which disappeared on pressure. Subsequently the pains in the muscles became more severe, and the case developed as one of typical **trichinosis.** No difficulty was experienced in finding the parasites in the muscles.

Thornhill[5] reports upon the extreme frequency of the **anchylostoma** as a parasite of man in India, Assam, and Ceylon, quoting extracts from reports of Dobson and McConnell of Assam and Calcutta. The figures show that the parasite is enormously distributed, and has been found in the stools of hundreds of healthy-looking persons. From this Dobson inferred that the parasite is quite harmless, but, as Thornhill points out, the duration of the parasitism and the number present have much to do with the occurrence of the symptoms, as has also the health of the person. Thornhill holds that it is one of the most dangerous of human parasites.

[5] Indian Med.-Chir. Rev., Oct., 1895.

Turner[1] has experimented with all the methods recommended for treating anchylostomiasis, and has determined that the only valuable drug is **thymol,** administered in large doses according to the recommendation of Sonsino. After strict milk diet for a day or two an aperient is administered, and the following morning ½ g. to 1 g. doses at hourly intervals, followed by a saline. This treatment must be repeated two or three times at intervals of a week or more until the eggs have disappeared from the feces. Alcohol in any form must be prohibited during the treatment. In some of the cases several hundred worms were expelled.

Austin Flint[2] reports a case of **chyluria** due to the **Filaria sanguinis hominis,** cured by the use of **methylene blue.** The patient was a West Indian aged 22. The urine was opaque and milky, and showed no tendency to precipitation. Its specific gravity was 1014; it was acid and contained 0.2% of albumin, but no sugar. There were abundant fat-globules and chyle-corpuscles, but no casts. The filariæ were very numerous in the blood taken at night. Two gr. of methylene blue were given every 4 hours for a day, when the urine became clear, but intensely blue, and the blood was almost free of parasites. This continued until the eighth day, when the chyluria reappeared, and on the ninth day the blood contained numerous parasites. The treatment was resumed the tenth day and continued 5 days. The urine became normal and the parasites disappeared, and the patient has remained well for a year.

Henry[3] reports a case of indigenous parasitic **chyluria with Filaria nocturna** in the blood. The patient developed chyluria on the third day after childbirth, the urine containing blood and mucous coagula. She had in childhood suffered from two chronic abscesses, and about a year before this observation from an attack described as malaria fever. Filaria embryos were found in the blood examined at 10 P. M. They were never found in the mother's milk or in the blood of the infant, and very rarely in the daytime. Leeches were applied in order to test the question as to whether they can act as intermediate hosts, but as the filariæ died as quickly in the body of the leech as upon the glass slide, Henry concludes that these animals do not act in this manner. Quinin and ergotin were without apparent effect. Thymol caused the chyle to disappear from the urine for 7 days, although the filariæ during this period were found abundantly in the blood. Methylene blue was finally employed, 2 gr. being given every 3 hours. It was continued until the urine and feces were stained a deep blue. The serum of the blood was also blue, and the filariæ showed an exceedingly faint bluish tinge, but their vitality was unimpaired. Upon the theory that another infection might destroy the parasite, the patient was vaccinated shortly after admittance to the hospital, but without result as far as the filariæ were concerned. Henry believes that in this case infection occurred in Florida, where the patient had spent the previous year, and expresses opinion that all treatment is futile.

RÖNTGEN SKIAGRAPHY.

[The interesting discovery of Prof. Röntgen promises to be of great usefulness in practical medicine. It is, of course, most immediately applicable in surgical diagnosis, and particularly in the recognition of fractures, dislocations, and other affections involving the bones. A number of investigators have, however, devoted themselves to the study of the uses of Röntgen skiagraphy in the diagnosis of organic diseases or affections usually falling to the care of medical men. As yet no positive progress can be reported, though a number of interesting communications have appeared. A few of these are referred to below. It seems desirable to refer to the work of Williams of Boston, who has contributed several important papers[1] touching upon the applicability of the Röntgen rays in the diagnosis of pulmonary affections. We have ourselves conducted certain investigations in the same direction, and have obtained most encouraging results in cases of intrathoracic aneurysms. These studies, however, have not yet been published, From present knowledge it may be confidently asserted that pulmonary lesions will soon fall into the domain of the conditions recognizable by the Röntgen method.]

Leo[2] discusses the value of the Röntgen rays in internal medicine, and in particular has investigated the permeability of solid calculi for these rays. He found that uric-acid, cystin, and cholesterin stones, two of each kind, were almost equally impermeable. He estimated the specific gravity of each calculus, finding the uric-acid stones 1.350 and 1.564, the cystin stones 1.420 and 1.310, the cholesterin stones 1.047 and 0.825. It is evident, therefore, that the mere specific gravity does not determine the permeability, and he suggests that certain tumors may be discovered by this method, in view of the fact that a substance of the light color and translucency of cystin obstructs the rays.

Huber[3] remarks that in various swellings of the joints it may be impossible to determine by palpation whether the changes lie in the joint-ends, in the cartilages, or in the soft parts. The Röntgen rays serve a useful purpose, and the author details several cases of chronic rheumatism and of gout in which the osseous or gouty nodules were satisfactorily outlined. The uric-acid deposits of gout allow the rays to pass through fairly well.

Hoppe-Seyler[4] refers to the use of the Röntgen rays in the diagnosis of arteriosclerosis. In a case of fibrosarcoma of the leg the radiograph showed irregularities in outline and variations in thickness of the anterior and posterior tibial arteries, indicating variations in the development of the atheromatous process. In another case the arteries of the hand were plainly visible, appearing as narrow bands alongside of and between the metacarpal bones. The pulsation of the vessels of course interferes somewhat with the accuracy of the result.

GENERAL SURGERY.

By W. W. KEEN, M. D., and JOHN CHALMERS DaCOSTA, M. D.,

of Philadelphia.

ASEPTIC AND ANTISEPTIC SURGERY, INCLUDING LIGATURES, SUTURES, DRESSINGS, BANDAGES, ETC.

"A New Method of Treating Wounds Antiseptically" is the title of an article by Schleich.[1] He discovered that when a solution of gelatin in water is evaporated over the vapor of formalin a product results which is hard, which is transparent, which is without chemical activity, and which is resistant to heat, moisture, and other ordinary influences. He found by experiment that when this formalin-gelatin was introduced into the peritoneal cavity of animals it was partly digested and partly encapsulated by connective tissue. When he introduced pathogenic bacteria into wounds, and at the same time introduced the powdered gelatin, no wound infection occurred. The applications were made to human beings. Suppuration was avoided, except when necrotic tissue was present and when specific infections existed. When applied to necrotic tissue the profuse secretion prevented the healthy cells from coming in contact with the gelatin, and hence forbade the elimination of formalin. In such infected areas the addition of a solution of pepsin and hydrochloric acid permits the formalin to be set free. Formalin-gelatin is prepared by adding 500 grams of pure gelatin in solution with 25 drops of pure formalin solution, and evaporating to dryness over formalin vapor. The product of the evaporation is powdered and is preserved in the presence of a drop of formalin solution. Formalin-gelatin can be mixed with lime salts and be used to replace bone defects. [During the past summer we have been testing this agent, which is furnished commercially under the name of glutol. It is a very valuable material in the treatment of wounds, of infected wounds, sinuses, ulcers, abscesses, boils, furuncles, and like conditions. During the fall of 1895 some experiments in closing bone defects were conducted in the surgical out-patient department of the Jefferson Hospital by DaCosta before the publication of Schleich's article: some of them had been set forth to classes, but enough observations had not been made to warrant publication before the appearance of the distinguished German's paper. One of the agents used was gelatin containing a small amount of formalin. Keen presented in the public clinic a case of necrosis of the tibia, and an attempt was

[1] Therap. Monatsh., 1896, No. 2.

made to close the cavity by the use of this gelatin. Schleich has made a complete investigation; has exhibited the proper method of preparation and use; has demonstrated its value in clean wounds and infected areas; has successfully filled cavities in bone; and has given a new and valuable agent to the surgeon.]

Haenel[1] discusses the problem, **"Is the disinfection of wounds possible?"** He believes that it has been clearly demonstrated that it is impossible to disinfect tissues with chemicals, and that the best means of surgical treatment is to provide free drainage for wound discharge and to absorb all secretions in dressings. The best means to provide for wound discharge is to keep the wound partly open. He was led to these conclusions by a study of his results after experimenting on 44 guinea-pigs. [This is in strict accordance with the well-known views of Schimmelbusch. There can be no question that infected wounds should invariably be drained. Although organisms in a wound cannot be killed by the use of chemical germicides, it is possible that the chemical which remains in the wound may prove antagonistic to toxines which arise from bacterial growth; hence we advocate the irrigation of infected wounds with corrosive sublimate. The common habit of irrigating aseptic wounds with corrosive sublimate is to be strongly condemned: it irritates the tissues, adds to discharge, and renders drainage imperatively necessary. Tillmanns has shown that antiseptics render cell division late in beginning and sluggish in progress—that repair is far quicker when antiseptics have not been used; in the wounds which follow an aseptic operation a firm cicatrix is formed in 8 days; in wounds in which bichloride of mercury has been used the granulation tissue has scarcely begun to be fibrous in 8 days. It is never any use to irrigate fatty tissue (as the breast) with antiseptics. The oil renders it impossible for the chemical to reach microorganisms, and the irritant agent is apt to induce subsequent fat-necrosis.]

Kane[2] calls attention to the value of fireproof **asbestos as a surgical dressing.** He maintains that on account of its indestructibility when subjected to high temperatures it is the only material which as a dressing can be rendered absolutely aseptic, while the variety of forms in which it is manufactured gives us materials which possess all the attributes of cotton fabrics as used in surgery, being even more satisfactory. Asbestos dressings can be kept as carelessly as if they were germ-proof. They may be carried around in any form of parcel or handbag, and may be even spattered with blood or filth, and yet can be rendered absolutely pure in less than two minutes by throwing them upon the coals or into the blaze of an ordinary kitchen fire. Kane now carries with him a compact parcel containing a supply of dressings of every sort. [It seems to us that Dr. Kane has contributed a fact of some value. To be able to obtain at any time and in almost any place a safe aseptic dressing is certainly most important, and he proves that asbestos is such a material. We lack personal experience, but think this method promising. If a demand is established for asbestos, beyond question finer prepa-

[1] Deutsch. med. Woch., 1895, No. 8.

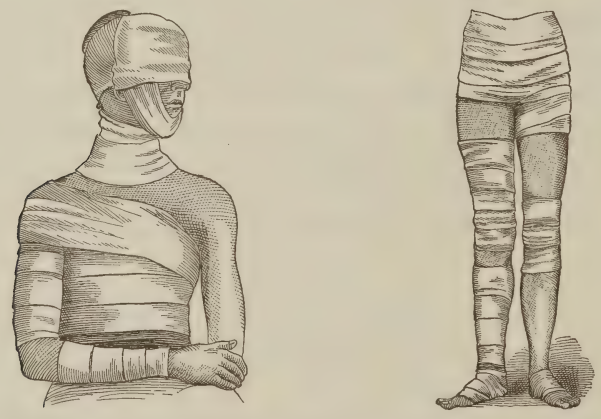
[2] Jour. Am. Med. Assoc., Dec. 7, 1895.

rations of it will be manufactured. The use of such dressings would save much money to large hospitals.]

"The Treatment of Aseptic Wounds without Bandages or Dressings" is the title of an article by Mackenzie.[1] He says that bandages are uncomfortable, are costly, and are liable to become displaced—that the essentials in the healing of a wound are—1. To maintain the parts at rest and the raw surfaces in close and constant apposition; 2. To prevent contamination of the wound from external sources; 3. To get rid of the wound discharges. He retains the raw surfaces in contact and the parts at rest by the systematic employment of buried catgut sutures. The raw surfaces are laid together in the position they are intended to assume. The points of contact are noted, and sutures of catgut are inserted through the raw surfaces, never penetrating the skin. These sutures are inserted a sufficient depth, and the opposing surfaces are then drawn firmly together. This is done systematically from the bottom of the wound to the skin-edges, the separate sutures being in rows, and the number of sutures in each row varying according to the ease or difficulty with which the raw surfaces can be maintained together. Even fine catgut applied by this method will maintain the parts in contact long enough to ensure adhesion of the surfaces before absorption of the catgut has taken place. The skin-edges are brought together and maintained in apposition by a continued catgut suture, including but a small extent of the cut cutaneous edges. A solution of celloidin is applied over the line of skin incision and for a half inch either side of it. This solution dries quickly, and leaves a thin transparent and adherent film which is sufficiently elastic to adapt itself to the wrinkles produced by movements of the parts. The solution of celloidin is made by dissolving 1 part of celloidin in 4 parts each of absolute alcohol and sulphuric ether. As the celloidin will not set in the presence of water, the wound after it is sutured should be covered for a few minutes with a piece of lint wet in carbolic solution, which lint is left in position until the patient is placed in his bed. By this time oozing from the skin stitch holes has ceased. The wound and surrounding skin are then carefully dried with a piece of lint soaked in rectified spirit, and then with a piece of lint soaked in absolute alcohol, and while the part is still moist with the absolute alcohol the celloidin is painted upon it. No bandages or dressings of any sort are required. The discharged blood from the aseptic wound is absorbed; the wound also absorbs its own discharges, and no contamination can take place from the outside. The post-operation oozing which is so common after ordinary methods of wound closure is to a large extent prevented by the firm contact of the raw surfaces brought about by the buried sutures; but when this oozing does occur there is no more need of drainage than in an ecchymosis or a hematoma produced by a blow with the skin intact. In some few cases it may be desirable to provide means of drainage. In order to secure this before the wound is closed, a small hole is made through the skin and subjacent tissues at its most dependent part, and as far

[1] Brit. Med. Jour., Feb. 1, 1896.

away as possible from the skin-edges of the wound. A piece of drainage-tube is passed into the wound, which tube is to fit very tightly the hole in the skin. The portion of the tube which is to be *in* the wound should have been perforated; the portion which is to hang out should be unperforated. The piece of unperforated tubing outside of the wound is introduced into a bag made of gutta-percha tissue containing sponge soaked in a strong antiseptic. The mouth of the bag is closed on the tube and glued to the tube by softening the gutta-percha with chloroform. In some cases it is advisable to paint the celloidin about the drainage opening and the tube at this point, but usually it is tight enough without doing so. If the wounds are not aseptic, and there is no possibility of healing by first intention, the above method is of no use and cannot be employed. The advantages of this method are very striking when the wound is near one of the natural orifices of the body, where dressings and bandages are very uncomfortable and fail to protect the wound. In wounds about the face this method is particularly successful.



[The value of buried sutures in many cases is beyond question. They should never be used in infected wounds, and should only be employed by surgeons who are sure of their capacity to obtain asepsis. Novices and bunglers will never succeed in safely employing them. The value of buried sutures has been long and ably advocated by Dr. Marcy of Boston. He no longer uses catgut, because it is difficult to disinfect with certainty, because it does not last long enough, and because it is structurally weak and stretches when it is moistened, and hence often fails to maintain the wound surfaces in apposition. He now uses tendon sutures, especially kangaroo tendon. This structure can be asepticized with certainty, and is extremely strong. Kangaroo tendon lasts in the tissue for 60 days or more, and is replaced by fibrous tissue, which acts as a sort of permanent buttress against separation of the wound.

Buried tendon sutures are of especial value in the radical cure of hernia. Celloidin is a concentrated collodion, but ordinary collodion answers all purposes. We see no especial use in the rubber bag to catch the wound fluids, and would fear its displacement.]

Gigli[1] gives us a method for the easy **removal of plaster-of-Paris bandages.** After applying cotton about the limb a layer of moist parchment paper is put above this cotton. A large sized cord greased with vaseline is placed upon this cotton in the direction that one would need to saw to open the plaster. Over this the plaster is put on. When in the course of time we are ready to remove the plaster the cord, whose ends project beyond the bandage and have been tied together, is loosened, and one end tied to a thin steel wire which has been nicked at intervals by means of a file. The wire is then drawn through in the cavity formerly occupied by the cord. Each end of this wire is attached to a handle, and the plaster can be readily sawed through, after which it is removed. [Several trials assure us that this method is practically useful and saves much time and trouble.]

[1] La Semaine méd., No. 3, 1895.

Fox[1] contributes an article on "A System of **Circular Bandaging.**" He states that 16 years ago an elastic tubular bandage was first used by him and recommended in the treatment of eczema and ulcers of the leg. He says that pure rubber applied to the edematous surface often produces brilliant results, but it is liable to cause in the delicate skin, and especially in hot weather, considerable irritation. Recently various forms of elastic webbing have been recommended for bandage purposes, and where simple pressure is required this webbing, being light and porous, has decided advantages. Of the use of elastic webbing in roller form nothing need be said, but he desires to call attention to the use of this webbing in the form of circular or garter bandages. These can easily be made by cutting the webbing in pieces of varying length and sewing the ends together, thus making elastic and tense garters of varying size. With a supply of these at hand almost any part of the body can be rapidly and strongly bandaged, and any degree of pressure can be applied which is apt to be required. Save where the bands overlap at the margin there is but one thickness of bandage, and no ordinary muscular effort upon the part of the patient lessens or displaces it. The accompanying illustrations exhibit the circular bandage as applied to various parts of the body (Figs. 5, 6). It is a great convenience for the retention

FIGS. 5, 6.—Circular bandaging (Fox, in N. Y. Med. Jour., Nov. 9, 1895).

of dressings in skin diseases, and the steady pressure which it exerts in many instances reinforces the value of the ointment applied to the skin. It is very efficient in varicose veins of the leg, and is a valuable substitute for knee-caps, anklets, and other joint bandages. It is well to have a supply of bands of various sizes at hand. With a tape measure the circumference can be ascertained and bands selected an inch or more smaller than the part, according to the degree of pressure required.

A new method of **bandaging the thumb** is discussed by Selva.[2] He says he has devised a method of bandaging the thumb: the length of bandage is 4 to 6 meters, and the width from $2\frac{1}{2}$ to 3 cm., according to the size of the

[1] N. Y. Med. Jour., Nov. 9, 1895.

[2] Med. News, Sept. 28, 1895.

hand. The hand is held in a position of semipronation, the thumb pointing upward and being abducted at an angle of 50°, so that the end of the distal phalanx is in line with the heads of the second and fifth metacarpal bones.

"The first stage of the application of this bandage consists in covering the terminal phalanx: the initial end is applied to the outer lateral surface of the second phalanx of the thumb near its base, and the roller is carried along the surface over the palmar side of the pulp of the distal phalanx to the inner lateral surface of the second phalanx; this turn is held in place by means of the index finger and thumb of the left hand of the operator; then the roller is returned in a *recurrent* form to the place of origin; this last turn should overlap the preceding one, and should be placed in as dorsal a position as possible; then the roller is directed downward and inward over the dorsum of the terminal phalanx, and is turned around the very tip of the pulp, forming a loop that will cross at a point corresponding to the center of the nail. Having thus covered the terminal phalanx, the roller is carried over the dorsum of the hand as low down as the head of the fifth metacarpal bone, the thumb all the time being held *abducted;* it is then turned over the palm of the metacarpus to the dorsal surface of the terminal phalanx, at the point of the first crossing, thus forming a figure-of-8 turn. This turn can be repeated over itself if the first one is not firm enough for starting. Then a series of successive figure-of-8 turns are made, each overlapping its predecessor and being about half a centimeter apart, forming an *ascending spica;* these turns are carried as high as the carpometacarpal articulation, and the bandage is ended by pinning it at the palmar surface of the ball of the thumb or by splitting and tying it around the metacarpus.

"This bandage is essentially a figure-of-8 form, the *smaller* or *lower* loops of which go around the first and second phalanges and part of the ball, and the *larger* or *upper* loops pass and overlap each other around the metacarpus and upper portion of the ball of the thumb. The bandage can be applied as high as necessary, and in order to completely cover the very highest portion of the ball the lower loops should be applied nearer together, or they can be repeated over themselves at the palmar surface of the base of the second phalanx, whereas the upper loops can be applied successively in an ascending form over the surface of the ball. Of course if there is no indication the *recurrent* portion of the bandage may be omitted, in which case the roller is started by one or two circular turns around the *end of the distal phalanx,* and then the rest of the bandage is applied as before. If after starting the roller should be directed first over the *palmar* surface of the metacarpus in making the upper loop, the crossings of the figure-of-8 turns will be situated on the palmar side of the thumb.

"It will be noticed that these figure-of-8 turns not only overlap themselves, but they also exert an *ascending compression,* which adds strength to the bandage and produces efficient immobilization of the thumb. As these turns are being applied, the thumb, which originally was in a position of

abduction, is gradually approached to the metacarpus, and it becomes more and more *adducted.*

"This bandage, unlike the others that have been previously described, does not begin or end at the wrist: it is a bandage that is applied to the phalanges of the thumb and to the metacarpus, and consequently the motions at

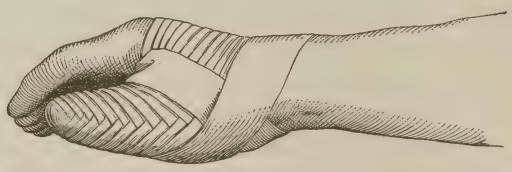


FIG. 7.—Selva's thumb-bandage applied (Med. News, Sept. 28, 1895).

the wrist joint do not interfere with the efficiency of the appliance. Provision is made by this bandage for completely covering the terminal phalanx of the thumb." Figure 7 shows this bandage applied.

"Sterilization of Catheters" is the title of an article by R. W. Frank.[1] He employs for this purpose the vapor of formalin. The catheters are placed in a glass jar, the bottom of which is perforated with holes. This jar is placed in a cylinder which contains formalin. Perfect sterilization occurs in 24 hours. The sterilization is permanent if the catheters are kept dry, and this can be accomplished by keeping them in a glass cylinder in a vessel which contains the chlorid of calcium.

[Guyon has for a number of years used sulphurous acid to sterilize woven urethral instruments. The instruments are first scrubbed with soap and water, and cleansed also on the inside, and placed, separated from contact with each other, in a hermetically sealed apparatus. They are then exposed to sulphurous acid for 48 hours. The subject of the methods of sterilization of urethral instruments is very ably discussed in an editorial in the Therapeutic Gazette, May 15, 1896.]

Pryor[2] writes an article on how to make **iodoform-gauze.** The fine gauze is sterilized by steam and then dried. After drying it is soaked in a 20% ethereal solution of iodoform for about 10 minutes. It is then wrung out, the gauze is placed in a basin covered with a towel and left for about 12 hours in a warm room, by which time the ether will be found to have completely evaporated. The gauze is now of a greenish-blue color, and will show free iodin if tested with starch. In this state it is not fit for use. It must be soaked for 12 hours in a 1 : 4000 watery solution of corrosive sublimate. This restores the yellow color of iodoform. The gauze is now wrung out dry and preserved in glass jars. This method disseminates the iodoform in every cell of the cotton fiber. Such dressing will not poison, as the iodoform will not be absorbed. When wound discharges and blood come in contact with the gauze it again becomes greenish blue by the setting free of iodin, so the dressing remains sterile even when saturated. The avoidance of the use of glycerol

[1] Berl. klin. Woch., No. 44, 1895.

[2] N. Y. Med. Jour., May 18, 1895.

is a great advantage, as serous exudation is not produced from the walls of cavities. Re-dressing is necessary at intervals 3 times as long as when ordinary iodoform-gauze is employed. It is nonirritant, it is antiseptic, and remains sterile even when completely soaked. He states that he uses a piece 5 yards long and 1 yard wide in the puerperal uterus. To obliterate the pelvic cavity he uses a piece 16 yards long and 4 in. wide. After resection of the sacrum he uses a piece 9 yards long and 4 in. wide. He has used this material for 5 years, and in not one case has he seen poisoning ensue.

Hans Vollmer[1] advocates the **sterilization of catgut** with formalin. This method was first advocated by Kossman, who soaked the catgut in a 2% watery solution of formalin for 24 hours, and then kept it in a .5 of 1% solution of the same agent. Vollmer has modified the process of Kossman. He cuts the raw gut the length which is desired, wraps each piece singly in filter paper soaked in a 2% solution of formalin for 24 hours. The catgut is dried at a temperature of 140° F., and the gut preserved dry until needed, when it should be soaked for a few minutes in a sterile fluid. Saul[2] advocates a method of sterilizing catgut which is based upon the studies of Repin and others. He determined that the following mixture was the best in which to boil the gut: 85 parts of ethyl-alcohol, 5 parts of liquefied phenol, and 10 parts of distilled water. He boils the catgut in this fluid in an apparatus which maintains the solution in its concentrated form and prevents very high pressure, and maintains the boiling point at the same degree. It is boiled for 15 minutes, which boiling completely sterilizes the catgut and in no wise injures its strength. [We have used during the year with much satisfaction the palladium catgut of Johnston, the preparation of which was set forth in the *Year-Book* for 1896, p. 340.] Clark[3] advocates in very strong terms the sterilization of catgut by cumol after the method of Krönig. Clark states that a great many methods of preparation are unreliable, and that outbreaks of infection have been traced not infrequently to the catgut used in cases. Koch showed us that commercial catgut as it is received from the manufacturer is rarely infected with pyogenic organisms, which accounts in a large measure for the absence of infection following the use of catgut prepared by even questionable methods. Hence many surgeons, losing sight of Koch's observation, claim to obtain satisfactory results from the employment of catgut which is open to the gravest objections from a bacteriological standpoint. In 1879 an outbreak of infection occurred in the service of Zweifel which was traced by Koch to the suture material, and Zweifel's strong prejudice against the Listerian method of sterilization by carbolized oil caused a large number of surgeons to abandon catgut. Kocher in 1881 introduced juniper oil as a sterilizing agent, but so many cases in his hospital became infected that he published an article against its use in any form, the article being termed "Fort mit dem Catgut."

In January, 1893, an epidemic of infection occurred in Kelly's wards in

[1] Centralbl. f. Gynäk., No. 46, 1895. [2] Berl. klin. Woch., Jan. 13, 1896.
[3] Johns Hopkins Hosp. Bull., Mar., 1896.

the Johns Hopkins Hospital which he believed to be due to catgut prepared by boiling in alcohol under pressure. Unfortunately, the whole supply of suspected catgut was used up in the last infected case, and in consequence bacteriologic proof could not be obtained. But Kelly was so firmly convinced that the catgut was the infecting agent that he discarded catgut and for two years relied entirely upon silk. A great number of chemic methods of sterilization have been suggested, but all are open to the objections of either failing to render the catgut harmless or weakening its strength or so impregnating it with irritants that it acted as a local irritant when placed in the tissues. Unquestionably, the most perfect means of sterilization for surgical purposes is heat. Until 1888 it was considered impossible to raise any form of animal ligature to a temperature sufficiently high to render it sterile without making it brittle. But in the above-mentioned year Reverdin and Benckisser brought out methods of sterilizing by dry heat. Reverdin states that it is not the oil in gut, but the hygroscopic water, which causes it to become brittle when heated. After this water is driven off by dry heat at a temperature of 70° C., a temperature of 150° C. can after this be employed without weakening the gut. A complicated apparatus is necessary, consisting of the hot-air oven and the thermoregulator. After these two investigators others sought for a liquid which has a sufficiently high boiling point to sterilize catgut. Brunner found that the boiling point of xylol was 136° to 140° C., and adopted this as the sterilizing agent, but Krönig found spores present in catgut which were more resistant than anthrax spores, with which Brunner had experimented, and these spores require a greater temperature for their destruction than can be obtained by boiling xylol. Krönig found that cumol, a hydrocarbon compound, had a boiling point of 168° to 170° C., and he substituted it for xylol. Krönig's method is as follows: 1. Roll the catgut into rings; 2. Dry it in a hot-air oven or over a sand bath for 2 hours at 70° C.; 3. Heat it in cumol to a temperature of 165° C. a little short of the boiling point for 1 hour; 4. Transfer to petroleum benzene for permanent preservation. A bacteriologic study of this method made by Dr. Clark proves that cumol perfectly sterilizes the catgut, but that the transference to benzene is open to serious objections, because benzene is not germicidal.

[In spite of Koch's observation that commercial catgut rarely contains pyogenic organisms, Lowenstein and others maintain that it often does.[1] Kocher has never returned to catgut. Within a year he has presented a record of goiter-operations. This record shows that primary union was obtained in 35% of the cases when catgut was used, and in 85.7% of the cases when sterile silk was used. He has now abandoned aseptic sutures, uses silk which has been antisepticized by an alcoholic solution of corrosive sublimate, and invariably obtains primary union. Halsted and other operators use silk, and they make out a strong case. In regard to the preparation of catgut by dry heat, Rydygier's method of employing it is said to entirely prevent brittleness. This method is in use in the Cracow clinic.

[1] Arch. f. klin. Chir., Bd. 1, Heft 21, No. 95.

The gut is wrapped in filter paper and placed in a cool oven, which oven has openings at the top. The oven is gradually heated to between 70–80° C., is kept at this temperature for half an hour, when the temperature is raised slowly to 120° C. For half an hour the temperature is caused to oscillate between 120° and 130°, and is then slowly raised to 160°, and caused to oscillate for half an hour between 158° and 163°. The oven is then allowed to cool (A. J. Richer). This method is efficient, but long and troublesome. We have tried cumol catgut and find it strong, smooth but not slippery, perfectly aseptic, and entirely reliable.]

Binnie[1] sets forth a method of **preparation of chromicized catgut.** It is an old method modified in many details. The catgut is cut into lengths of from 4 to 8 feet, is washed in soap and water, and each length is wound on a glass reel. It is placed in a 1% watery solution of chromic acid, and left in this from 4 to 6 hours, and this solution is strained off through aseptic gauze. A large quantity of sulphurous acid is then poured over the catgut, and the sulphurous acid is strained off after 12 hours. The acid is now replaced by a 2% solution of salicylic acid in commercial alcohol, and the gut in the salicylic-acid solution is placed in a water bath and boiled for 15 minutes. The alcohol reaches a temperature of 175° F. when the vessel is open, but if the stopper is applied loosely a higher temperature may be obtained. If the bottle is closed by a very loose plug of cotton, the temperature can be raised to 189° F. These ligatures are now placed in small sterilized bottles with rubber stoppers, or bottles are filled with salicylated alcohol, and after being filled are again boiled in a water bath for a few minutes and the stoppers pressed home.

Arangino[2] advocates the use of **parietal peritoneum** as a material **for sutures and ligatures.** He takes the peritoneum of horses or cattle, cuts it into strips, twists the strips into cords, and dries them for 4 days. He treats them with ether to free them from fat, soaks them in a 2% solution of mercuric chlorid and alcohol, and keeps them in a weak solution of mercuric chlorid.

A preparation known as **cutin** is recommended by Lusteck[3] as a substitute for silk or catgut. It is prepared from the gut of cattle by removing the serous and mucous membranes from the muscular layer and digesting this layer in 20% pepsin solution. The membrane is treated with trioxybenzoic acid and hydrogen dioxid. Antiseptics may be added before we harden it. This preparation is soft, smooth, can be absorbed, and can be sterilized by the use of dry heat.

Marcy[4] read a paper upon **"The Buried Tendon Suture"** before the Southern Surgical and Gynecological Association. He was the first to suggest this suture, advocating catgut in 1870 and tendon in 1880. [There can be no question that these sutures constitute an important addition to the materials of surgery, and that they are superior to any other materials hitherto

[1] Kansas City Med. Index, June, 1896.
[2] La Clin. Chirurg., Aug., 1895.
[3] Aerzte Rundsch., 1895, v. p. 440.
[4] Therap. Gaz., Apr., 1896.

employed for like purposes. Our chief experience with the buried tendon suture has been in the radical cure of hernia, and in these operations it is invaluable. We have also employed it to hold portions of bone in contact, especially after fracture. We strongly object to keeping it in any oil whatever, and prefer to keep it in alcohol. No oil is certainly sterile.]

Colombini [1] discusses **the local action of salol.** He states that in the presence of alkali or of living tissue salol breaks up into salicylic and carbolic acid, and we get from these acids in this nascent form antiseptic action without irritation effect. A good solution for salol is vaseline, and the combination of salol and vaseline does not irritate the cutaneous surface near inflamed ulcers. This remedy, the author maintains, will be very valuable as a nonirritant antiseptic. [We have used the ointment, and with some success, upon eczema and ulceration, and have employed the powder as a dusting powder for wounds, ulcers, cutaneous surfaces, and sinuses. It does not seem to be as efficient as acetanilid. The claim that it is nonirritant is certainly true. The ointment of salol and vaseline has been used to anoint bougies, but we do not approve of vaseline for this purpose, as portions of the ointment may be left in the bladder, and a case has been reported of a vesical calculus with a cosmoline nucleus.]

Loretin is a new antiseptic which is discussed by Herbert Snow of London.[2] This agent was discovered by Claus of Freiburg. It is a bright yellow, odorless, crystalline powder but slightly soluble in water and alcohol. Ammelburg proved loretin to be a powerful germicide, much superior to iodoform. Schnesinger has used loretin extensively, and with great benefit in burns and all sorts of operations (herniotomy, resection of upper jaw, etc.), and has never seen toxic symptoms. It does not irritate the skin at all; the scar from a burn dressed with loretin is slight. Loretin is used as a dusting powder (alone or mixed with starch, chalk, or magnesia), as collodion (2–10%), in pencils of cocoa butter (5–10%), in ointment (5 or 10%) with vaseline or lanoline, in solution (1–2% of free acid or 1–2% of sodium salt), as gauze impregnated with the calcium salt. Snow's own experience is confined to the powder, which he uses unmixed. It does not irritate in the slightest the skin or a granulating wound. It instantly destroys the fetor of the most malodorous sore. Insufflated into a large wound, it will prevent suppuration. Snow has used it in 60 cases, mainly operations upon the breast and axilla, and considers it an ideal antiseptic and deodorant. It is absolutely nontoxic.

Among a large number of **new antiseptics** which have been suggested we would name the following:

Oxycyanid of mercury, first recommended by Chibret.[3] It is used in the strength of 5 : 1000. It does not attack the hands nor injure instruments, and is quite as efficient as corrosive sublimate. It must not be used to wash out cavities if there is any chance of fluid remaining.

[1] Brit. Med. Jour., 1895, No. 1818, p. 71. [2] Ibid., Dec. 2, 1895.
[3] Monod and Malgaigne in Progrès méd., Oct. 26, 1895.

Fluorid of sodium[1] is used by Blaizot to cleanse the mouth and skin; the strength solution employed is ½ to 2%. It is used for vaginal injections and for the treatment of erythema neonatorum. Because of its power to dissolve albuminous substances, Luffier of Paris uses it in certain cases of cystitis.

Calcium permanganate[2] is not toxic, is not caustic, and is claimed to be as certainly germicidal as is mercury chlorid. It is claimed to be 100 times more active than potassium permanganate.

Argonin[3] is not irritating to mucous membrane, does not penetrate the tissues deeply, is not precipitated by albumin or sodium chlorid, and will kill gonococci.

Lannaiol[4] is an iodocresol, and is used as a substitute for iodoform. The writers claim that it is free of odor, nonpoisonous, and unirritating.

R. iodocarbazol.[5] This compound is insoluble in water, but is soluble in ether, alcohol (hot), chloroform, and acetic acid.

Lignosulphit[6] is a liquid obtained as a side product during the manufacture of cellulose from pine wood.

Parachlorophenol[7] can be used in 1 and 2% solution as a substitute for mercury.

Veratrol[8] is an oil resembling guaiacol in some of its actions, lowering febrile temperature when applied to skin, and being much less toxic than guaiacol.

Sugar[9] is advised as a useful antiseptic in emergencies. Concentrated saccharine solutions prevent the growth of saprophytic and pathogenic organisms. Wounds can be dusted with sugar or dressed with sugar contained in bags. [The best emergency antiseptic we learn of is mustard, a material the great value of which has been set forth by Roswell Park (see *Year-Book* for 1896, p. 339). Park says scrub the hands for 5 minutes with a mixture of soap, cornmeal, and mustard flour, and the hands will be rendered absolutely sterile. Park invariably uses mustard to prepare himself for an operation. It will also remove the odor of decay and the smell of iodoform. Park was one of the first to try sugar and mustard.]

Jaworski of Warsaw contributes an article upon **steam as a hemostatic and antiseptic agent.** He states that it is cauterizing, anesthetic, deodorizing, hemostatic, disinfecting, and aseptic. It checks parenchymatous bleeding. The experimenter removed portions of the liver, of the kidney, of the lung, and of the uterus in animals without loss of blood. He has used it in man in resection of the knee, removal of a mammary gland and various tumors, amputation of the cervix uteri, removal of myoma of the uterus, and many other operations. He uses an apparatus for distilling water. The steam

is applied for half a minute to a minute. He considers this agent expressly valuable in gynecologic operations. [It is hard to control, and we cannot limit the extent of damage done to the sound tissues.]

Adhesol is a form of surgical dressing strongly recommended by Dufau.[1] [What special advantage adhesol possesses over collodion we do not know. The preparation is far more complicated than is that of collodion, and we do not believe a whit more efficient.]

Sänger[2] of Leipsic opposes the use of **dry sponges** in abdominal operations, because they injure the peritoneum mechanically, and as a consequence are liable to give rise to adhesions. He wrings sponges out in a solution of sodium chlorid and calcined sodium carbonate. This solution was originally recommended by Tavel. It consists of 7.5 g. of sodium chlorid, 2.5 g. of calcined sodium carbonate, and 1 liter of water. [The prevention of adhesions is a matter of great importance, but as yet our success in prevention is very limited. Sänger's proposition is entirely reasonable, and promises valuable results.]

ABSCESSES, SUPPURATION, SEPSIS, AND ERYSIPELAS.

Erysipelas.—Langsdorff[3] advocates the treatment of erysipelas by the local use of strong alcohol. Soft compresses of linen are saturated with alcohol, are covered with gutta-percha tissue, and are renewed every 15 or 20 minutes. In facial erysipelas cotton is used instead of linen, because it more readily adapts itself to the irregular contour. The redness and tension will often disappear within 12 hours, and after they have disappeared the intervals of application may be increased. Recovery is the rule in 2 or 3 days. Considerable dryness of the skin is apt to follow recovery, and for this lanoline is very valuable. [The great number of plans which have been proposed for treating erysipelas is proof that no one plan is entirely satisfactory. Most of the plans are complicated, and yet neglect an essential procedure. A seat of primary infection should always be sought for: it may not be discovered, but if it is discovered, it must be thoroughly asepticized. A very old plan of treatment holds its own as one of the best that can be employed; that is, every day paint the red area and the sound skin adjacent to it with tincture of iodin diluted with an equal bulk of alcohol, and then cover the part with lead water and laudanum. A bandage is then applied. The iodin is antiseptic, and the lead water and laudanum is astringent and anodyne; evaporation produces cold and the bandage exercises compression. Von Nussbaum's method—viz. the use of ichthyol—is certainly efficient. Constitutional treatment must never be neglected.]

The origin of the stitch-abscess is discussed by Lauenstein.[4] He has long been studying the occurrence of infection after aseptic operations, and has found many instances which could be explained only by believing that the infection was due to sutures or ligatures. He made bacteriologic

[1] Semaine méd., 1895, xv. p. cxxii.
[2] Centralbl. f. Chir., 1896, p. 191.
[3] Ibid., 1895, No. 8, p. 189.
[4] Beiträge z. Centralbl. f. Chir., No. 27, 1895.

studies in the case of 216 sutures and ligatures, and in these he found 64 which contained bacteria. He came to the following conclusions: 1. That clinical observations show that cases of suppuration do occur which originate from the catgut employed in the wound; 2. It cannot be certainly said in any instance that the catgut has been the cause of the infection; 3. It is absolutely certain that the alleged sterile catgut of commerce often contains germs capable of development; 4. So long as this is the case catgut cannot be free from suspicion of causing infection in wounds. [Koch, the reader will recall, was of the opinion that commercial catgut rarely contained the organisms of suppuration, but Lauenstein differs from him. Kocher strongly affirms his belief that catgut is a frequent cause of infection: in his goiter-operations he had 65% of infections when he used gut, and has had only 15% since using silk. Halsted and Marcy both believe that catgut is frequently infected. That gut can be made sterile is certain; that it is frequently very badly sterilized is equally certain. We think the great percentage of infections obtained by Kocher is an indictment of his method of sterilization.]

Mammary Abscess.—Spencer[1] contributes a note upon the prevention of large mammary abscess by the expression of the milk. He tells us that in the operative treatment of these cases generally more than one incision has to be made, the sinuses are very long in healing, and in some cases the removal of the breast has been demanded. He tells us that in instances in which the breasts are extremely distended, lactation having been recently interrupted, suppuration will be prevented by the forcible expression of from ½ to 1 pint of milk. [In lactating women great care of the nipple will usually prevent the formation of breast abscess, as the causative organisms usually enter by means of the milk ducts. It is conceivable that these abscesses could arise in septicemia by infection of the blood stream, but this mode of origin is rare. Most observers teach that they are rarely due to lymphatic absorption from areas of nipple infection, because the lymphatics from the nipple are superficial to the mammary gland and run directly to the axillary glands (W. Watson Cheyne). An area of infection at the exit of the ducts can eventuate in the spread of organisms into the ducts (not an active absorption).] After squeezing out the breast nursing should be absolutely prohibited and the arm should be bandaged to the side. Spencer orders the women to frequently foment and squeeze the breast, and to take potassium iodid for a few days.

Sheild[2] contributes an article of great value upon the Causation and Treatment of Mammary Abscess. He feels assured that operative treatment as ordinarily conducted is not satisfactory. As regards the causation of these affections, though everybody associates them with lactation, yet instances occur which are quite inexplicable on these grounds, and it is here that special diagnostic difficulties arise rendering the subject of immense importance to the surgeon. When we consider the ordinary form of acute mammary abscess, figures clearly show its close relation to lactation. In a study of 200 cases admitted into St. George's Hospital, 169 were directly due to lactation and

[1] Lancet, Feb. 29, 1896.

[2] Ibid., May 2, 1896.

referred to sore nipples; 31 were due to other causes, and of these 8 were directly attributed to the blood; 1 was due to necrosis of the rib; and 22 were due to uncertain causes, but of these in 5 instances the abscess originated on the site of former abscesses, and in 3 there was suspicion that the disease was tubercular. As regards the time after parturition that a mammary abscess occurs, there is the greatest variability. Some of the cases occur as early as the 1st, others not until the 14th month. Birkett assumes that one half of the cases are associated with defective or sore nipples. Sheild believes that the average is far higher than this. In fact, he has never seen a case of acute mammary abscess in a young woman without being able to observe by the aid of a lens breaches of surface in the vicinity of the nipple by which organisms might effect an entrance into lymphatic channels. He was greatly struck with the infrequency of mammary abscess in Queen Charlotte's Lying-in Hospital; the cause of this infrequency was the great precaution taken by the physicians to ensure cleanliness of the nipples and of the infant's mouth. This is the first important proposition of his paper—that in the huge majority of cases acute mammary abscess, whether arising during lactation or not and in either sex, is due to absorption by the lymphatics of organisms which enter abrasions on the nipple or areola. [Most observers deny this on anatomic grounds (see previous paper, p. 212).]

Nocard produced tubercular mammary abscess by injecting tuberculous virus into the milk-ducts of a lactating goat, and Boissard in 1893 stated positively that milk-ducts could be infected by streptococci and staphylococci. Of course it is always open to doubt in these cases that some breach of surface does not really exist, and although the experiments of Nocard proved conclusively that infection by the ducts is possible, it certainly is not common. For 3 years Sheild has closely examined a number of cases of mammary inflammation and abscesses without finding a single case which he could certainly attribute to infection through the milk-ducts themselves, and he and Sherrington performed some experiments upon lactating goats and lactating rabbits which were purely negative in results. What the effects of gonococci upon the milk-ducts of the human subject may be it is impossible to prove experimentally, but one would imagine that purulent inflammation would readily result. Purulent inflammation of the milk-ducts must of course produce serious results in the infant. [Sheild makes out a strong case in favor of lymphatic absorption, but to our mind does not surmount the anatomic difficulties to accepting this view.]

The influence of blows in causing abscess of the breast is well known, and suppuration in the male breast is usually attributed to this cause. In 12 cases studied by Bryant, 8 were attributed to pressure or injury. In such instances it seems quite plain that a communication is established between the area of tissue containing extravasated blood, the resistance of which is impaired, and the external parts through the torn or injured ducts. Hence organisms may enter and produce ill effects. Abscess in the breasts of infants is quite common and is largely a preventable malady. It is commonly devel-

oped during the manipulations of ignorant nurses, who pull or rub the nipples until a breach of surface is effected. Suppuration in connection with new growths is extremely rare. Abscesses may be found in the neighborhood of ulcerated carcinoma. In very exceptional cases the cysts of sarcoma or adenoma may contain pus. Should they be artificially inflamed or inoculated with septic material by a dirty trocar, suppuration is not uncommon. In the days when caustics were employed to remove cancers of the breast abscess and cellulitis often arose. In nearly all our text-books abscesses are divided into the supramammary, the intramammary, and the submammary. In the supramammary the pus forms beneath the skin and the areola. The submammary form is extremely rare, but may arise as a sequence of caries of the rib or of empyema; often abscesses supposed to be submammary are really in the deeper part of the gland itself. A great majority of abscesses are in the substance of the breast. Great havoc is wrought by untreated suppuration in the breast. The abscess burrows and branches and forms pockets and recesses, multiple points, and sinuses. It very rarely happens that there is a fatal result from septicemia. [One of the editors (DaCosta) has seen a fatal case within one year.] In some cases destruction has been so great that amputation has been resorted to. Abscess of the breast commonly becomes constricted where the pus has burrowed through fascia or fibrous septa, the abscesses assuming in consequence an hourglass shape. This condition was long ago described by Velpeau. It shows itself as a subcutaneous swelling, and if it is simply treated by an incision radiating from the nipple, the discharge will continue indefinitely, because the main pus-cavity has not been freely drained.

Sheild considers the **influence of tubercle** in producing abscess of the breast. Sir Astley Cooper many years ago alluded to scrofulous tumors in the breasts of single women, which abscesses contained thin, watery, or curdy pus. The axillary glands are likely to become involved. Payne has related a very remarkable case of tuberculous abscess near the nipple of a child who subsequently died from general tuberculosis. The important question of the transmission of tubercle by a mother to her child is believed by many to be possible, though some think that Colles's law holds as true in tubercle as it does in syphilis. Powers has stated that there are 35 authentic cases on record of primary tuberculosis of the breast. Sheild has met with 6 cases. [Catelain has within the past year reported 2 additional cases, in both of which the axillary glands were enlarged. In 1 case he proved the diagnosis by injecting guinea-pigs with some of the caseous material obtained by the removal of the breast and the clearing of the axilla. The animals developed tuberculosis. Powers' article will be found in the *Year-Book* for 1896, p. 176. Gaudier and Peraire report 3 cases,[1] and claim that this brings up the total number of reported cases to 42. All 3 were recognized by finding the bacilli. Recinck says the diagnosis rests upon the histological examination and the finding of bacilli. In cases of circumscribed disease he extirpates the diseased area; in cases with axillary involvement he operates as for cancer.]

[1] Rev. de Chir., Sept., 1895.

It should be remembered that an acute mammary abscess is a preventable disorder if the medical attendant is careful as to the cleansing of the nipple and the mouth of the child, and if he is aware of the importance of attention and proper care of the nipples previous to marriage. In certain cases of maldevelopment of the nipples fissures or ulcers will arise, and in such persons abscess may occur in spite of the best care. Sheild then goes on to speak of the purely operative treatment of acute abscess. Of course the child must be weaned, the breast must be supported, the secretion of milk must be arrested by the administration of drugs, or the fluid must be expressed by massage and the exhausting pump. Beale advocates opening the abscess with a trocar and cannula and applying the exhausting bottle to the aperture. Sheild thinks such a treatment might be applicable to a small superficial abscess, but would oppose using it in deep-seated collections of pus. He is absolutely sure that the old treatment of a free anterior opening radiating from the nipple is essentially wrong. It leaves a scar on the front of the breast, and it opens the abscess-cavity in a position unsuitable for drainage. As a consequence these cases frequently are subjected to several operations until drainage-tubes are seen projecting through various openings.

Sheild in conclusion asserts his belief that breasts are removed too frequently for these affections, and that free drainage in the dependent position, with erasion and flushing, will in the majority of cases obviate the necessity of more serious operation. [We consider that Sheild's article is sound, practical, and conclusive. The old method of operating, by linear incision, is often, as every surgeon knows, extremely unsatisfactory. Gibson insisted years ago that the opening should always be at the lower portion of the breast. Sheild's method is his own, and commends itself to our judgment as a highly valuable suggestion.]

Lannois[1] describes **pyelophlebitis and abscess of the liver resulting from typhoid fever,** the bacillus of Eberth being discovered in the pus of the abscess. He tells us that abscess of the liver as the result of typhoid is extremely rare, and occurs in 1 out of 3680 cases. He divides abscess of the liver resulting from typhoid into three varieties: 1. Metastatic abscesses which take origin from some external area of suppuration; 2. Abscesses from typhoid ulcers of the bile passages; 3. Abscesses due to pyelophlebitis. The case he reports belongs to the latter class. The man was 28 years of age, and the attack of fever had passed away. He had been 3 days free from fever when he was seized with a chill, fever, and the evidences of pleurisy at the base of each lung. The abdomen was distended and there was great pain in the right hypochondriac region. The case was looked upon as tubercular peritonitis because of the pleurisy and the abdominal distention. The patient died in 3 days. The autopsy showed healed ulcers in the small intestine and some partly healed ones. There were antemortem clots in the portal vein, the splenic vein, and the inferior mesenteric vein, and the latter contained a number of abscesses. The pus when examined contained a variety of organ-

[1] Rev. de Méd., Nov., 1895.

isms, one of which strongly resembled the typhoid bacillus except that it liquefied gelatin. The author maintains that it was the typhoid bacillus, and the liquefaction occurred because of the impure culture.

[The *Year-Book* for 1896 shows that the gall-bladder may be attacked by typhoid bacilli.[1] It seems probable that Lannois is correct, and that the organisms were typhoid bacilli.]

Hayden[2] advocates the injection of iodoform ointment in **the treatment of suppurative adenitis of the groin.** He reviews the various surgical procedures which have been suggested for this condition; for instance, aspiration and iodin injections, incision and irrigation with iodin, incision and packing with iodoform. Helm cleansed the parts, anesthetized by ether-spray, drew off the pus with a hypodermic needle, washed out the abscess-cavity with a weak solution of phenol, filled the cavity with iodoform in glycerol, withdrew the needle, closed the puncture with collodion, and applied a dressing and a bandage. Helm substituted after a time oleic acid for the glycerol, and finally iodol for the iodoform. In 1889, Von Eichstoff presented the records of a number of cases which he had treated by injecting iodoform and ether. In the same year Fontan described the treatment of buboes by injections of iodoform-vaseline. He maintained that the average time of cure under the influence of this method was from 6 to 7 days. He advises that the parts be shaved and cleaned, the bubo opened with a lancet, and the pus forced out, the abscess-cavity irrigated with dilute Van Swieten's fluid, iodoform-vaseline injected in a glass syringe which has previously been warmed in hot water. A cold wet dressing is applied in order to solidify the ointment at the opening. In some few cases a second injection is necessary. In 1893, Otis strongly advocated the use of this method. Hayden has employed Fontan's method with great success, and strongly advocates its use.

Except in 2 cases, suppurative action and pain ceased after 1 injection. In these cases the injection had to be repeated because of slight reaccumulation of pus. This method should only be employed when the glands are thoroughly broken down, so that the iodoform may come in direct contact with all infected regions. This method will not succeed in every case, but it has many advantages in most cases over more radical procedures. The patient is not confined to bed; he is not required to take an anesthetic, and a very slight scar remains. If after one or several injections this method fails, an incision may well be made. [We have succeeded in some cases, but have more often failed. We usually apply treatment before the glands are entirely broken down; that is, a clean incision through sound skin, extirpation, and antiseptization. Incision made through sound skin leaves but little scar, especially if closed by Halsted's subcuticular suture.]

Richardson[3] advises the use of sugar in the dressing of **furuncles and carbuncles,** and maintains that it brings about rapid softening. He dusts it freely in the carbuncle and then applies flaxseed poultices. [The flaxseed

[1] Williams and Sheild and Gilbert and Girode, p. 239.

[2] Am. Jour. Med. Sci., Nov., 1895.

[3] La Sem. méd., xvi. p. xxvi., 1896.

poultice is an eminently undesirable application, and sugaring a carbuncle is a waste of time. The knife should be used, and at once, after the method advised on page 219 in the note upon Harding Tompkins's article.]

Lamarchia[1] has invented a delicate instrument to recognize **fluctuation.** It consists of a thin metal disk with a central opening. This disk is held by edges between the middle finger and thumb of one hand and pressed upon the surface. The tip of the index finger is lightly applied to the surface through a central opening, while the other hand is employed to give a tap upon the surface. He claims that the slightest wave can thus be recognized and that false fluctuation can be thus certainly excluded.

Galeazzi[2] has made a number of experiments upon animals to determine **the effect of shock upon the predisposition to septic infection.** Many writers have claimed that shock predisposes to it, but his experiments would indicate that shock does not favor infection, and he thinks it strange that the view should ever have been held because of the slowness of absorption which exists in shock. [In spite of the positive statement of Galeazzi, we are not prepared to abandon the usual view without positive evidence that it is wrong.]

Berlin[3] in reporting to the Société de Chirurgie the case of a woman who developed violent sepsis after a vaginal hysterectomy strongly advocated **the treatment of sepsis** by intravenous injections of artificial blood serum. In this case violent sepsis appeared 3 days after the operation, and on the fourth day the patient was apparently dying. She was given an intravenous injection of about 1 pint of artificial blood serum, and shortly afterward she was given almost 2 pints. Marked cyanosis was observed and the symptoms became very grave, but in a short time decided improvement began and the patient recovered. [Ségond has used injections of artificial serum for 4 years, and strongly approves of them. Monod and Michaux speak in favor of this agent. Lenier says the serum can be used subcutaneously as well as intravenously, and should be combined with bloodletting. These injections stimulate the kidneys in postoperative anuria, of which we ourselves have had a marked example recently.]

Lejars[4] has reported 3 cases of septic infection in which artificial serum was injected, and 2 of the cases were saved. An abstract of the article will be found in the Practitioner.

In 1 case Lejars gave 3 subcutaneous injections in 1 day, and the same the next day, 500 grams being given at each time. On the third day 1½ liters were given. For several days 2 liters were given daily, and they caused profuse discharge of urine and feces. In 7 days 26 liters were given. Lejars thinks this agent acts by causing the extrusion of a great amount of toxins and microorganisms by means of diuresis and diarrhea. Sometimes during the injection the patient has transient abdominal pain and dyspnea. Hayem's serum was used. It consists of sodium chlorid, 5 grams; sodium sulphate,

[4] La Presse méd., Jan. 1, 1896.

10 grams; distilled water, 1 liter; or about 40 gr. of common salt and 80 gr. of sulphate of soda to the pint.

Harding H. Tompkins[1] comments on the statement of Mr. Maberley,[2] who maintains that **carbuncles** heal better, more quickly, and are subject to less sloughing when they are uncut, and maintains that pressure is a valuable aid to treatment. Tompkins says that the great disadvantage in applying pressure is the difficulty in application and the pain. He advocates the application of pressure by painting all over and beyond the inflamed area with collodion in graduated thicknesses toward the center, and securing outlets for pus and thorough disinfection by boring into the center from several points by a charred lucifer match soaked in pure carbolic acid. The results, he maintains, have been extremely favorable. [We believe strongly in the necessity for incision. In the old days a crucial incision was made and a flaxseed poultice was applied. It is true that in some subjects this procedure was followed by an intensification of the constitutional symptoms and by a spread of the suppuration into the healthy tissues which were opened by the incisions. The introduction of antiseptic methods has profoundly altered the course of carbuncles. The surface should be cleansed. The carbuncle should be opened by crucial incisions, sloughs and infiltrated tissues should be removed by scissors and the curet, the raw surface ought to be seared with pure carbolic acid or dusted with iodoform, and the wound should be dressed with hot antiseptic fomentations. Some severe carbuncles require the application of the actual cautery or even excision of the entire area. (See under the heading Carbuncle in Warren's Surgical Pathology and Therapeutics.)]

Marmorek[3] has produced an **antistreptococcus serum** which he applied to cases of erysipelas. He used it upon 306 cases: 165 of these were severe cases, the mortality was 1.63%; and, as some of these deaths were due to causes apart from the disease, the real mortality was 1.2%. When the weaker serum was employed the mortality rose to 4.82%. The average mortality of its use was 5.12%. After the dose improvement in both general and local symptoms was noted in from 5 to 12 hours, and the temperature came to normal in 24 hours. If at the end of 24 hours the temperature was high, the injection was repeated. Patients treated with serum never developed albuminuria, and albuminuria when already present disappeared in from 24 to 48 hours after the commencement of serum injections. The dose varied from 10 c.cm. to 20 c.cm. More than 100 c.cm. were never given in 10 days. He claims very admirable results in the treatment of puerperal fever, especially when the infection is purely due to streptococci.

[Antistreptococcus serum has been used also in cellulitis, and has had, it is claimed, a beneficial action. (See Brit. Med. Jour., Dec. 7, 1895.)]

Dubreuilh[4] reviews this subject. An abstract of Dubreuilh's article is contained in The Practitioner, Mar., 1896.

Chantemesse publishes the following table:

[1] Brit. Med. Jour., Mar. 21, 1896.
[2] Ibid., Feb. 15, 1896.
[3] Ann. de l'Inst. Pasteur, Nov. 7, 1895.
[4] Jour. de Méd. de Bordeaux, Jan. 26, 1896.

	Patients.	Deaths.	Death-rate, %.
Number of cases	1055	34	3.22
Purely symptomatic treatment	145	5	3.45
Symptomatic warm baths	409	16	3.01
Serum of medium strength	297	5	1.70
Weak serum	107	7	5.54
Very strong serum	97	1	1.03

Local improvement in erysipelas begins in 24 hours, redness diminishing, spread ceasing, and pain abating. The fever ceases on the first day.

In puerperal fever as much as 100 c.c. of serum has been used in doses of 20–25 c.c., repeated once or even twice a day.

[It is certain that a person recovered from suppuration is in no degree protected from a subsequent suppuration. On the face of it, it seems improbable that there is any such thing as immunity natural, or acquired, to pyogenic infection. The real value of this treatment can be determined only by more extended observation conducted with honesty, care, and scientific scepticism.]

TUBERCULOSIS.

Tuberculosis of hernia is discussed by Tenderich,[1] who reports 3 cases, in 2 of which the hernial sac contained only serous fluid and the peritoneum of the abdomen was tuberculous. One of these cases died of pulmonary tuberculosis, but 2 remained in good condition 7 months afterward. The author was able to find 22 cases of this condition reported. He quotes Bruns to the effect that the hernial tuberculosis may be primary, but that, as a rule, it is combined with general tuberculous peritonitis; 14 of these cases were subjected to operation; 3 died as the result of operation; 4 recovered from the operation, but were not subsequently traced; 4 were well between 6 and 9 months after operation, and 3 were well between 1 and 2 years after operation. Most of the cases were inguinal hernia in the male. Certain diagnosis is impossible unless symptoms exist of general tuberculous peritonitis. [Jonnesco in 1891 reported 12 cases. In 6 of these cases the sac alone was diseased, in 3 cases the contents of the sac alone were diseased, and in 3 cases both the sac and contents were attacked. He advised removal of the sac and resection of the intestine when possible; if this is found impossible, he recommended reduction of the bowel. Not a few cases have been cured by simple incision, just as peritoneal tuberculosis has been cured by celiotomy.]

Cesar[2] comments upon Bidwell's report of 6 cases of **lupus** which were treated radically. He dissents from Bidwell's statement that Watson Cheyne was the first to excise lupus and practise immediate skin-grafting. Cesar states that he did this himself 20 years ago. He thinks excision is far better than curetting, and maintains that skin-grafting is unessential. [Excision has been practised often, but it was largely abandoned through the influence of Richard Volkmann, who was a firm believer in the sharp spoon and caustics, though he occasionally practised excision, followed immediately by a plastic operation.

[1] Deutsch. Zeit. f. Chir., 1895, xli. p. 220.

[2] Lancet, Apr. 6, 1895.

Volkmann's treatment is suitable for most cases, but Cheyne's method will limit deformity.]

Isnardi[1] advocates the local use of oil of turpentine in tuberculous lesions. He uses this in tuberculosis of the skin, in fistulæ, and in abscesses, combining it with vaseline. He advises that a fistula be first curetted, and an abscess be first aspirated. He packs abscesses with sterile gauze containing equal parts of vaseline and oil of turpentine, and reports 18 successful cases. [Turpentine was years ago given internally and by inhalation in phthisis. Possibly this use of it may have suggested its employment in fistula. In the treatment of sinuses and fistulæ we have obtained the most excellent results from the local use of two drugs—palladium bichlorid and pyoktanin. In some cases we use one and in some cases the other. A report upon palladium will soon be published.]

Primrose[2] strongly advocates the early **operative removal of tubercular glands.** He says that operative procedure is restricted to the localities in which the glands are accessible. The cervical glands, the axillary glands, the inguinal glands, and the glands along the iliac vessels can all be readily removed. The glands of the thoracic and abdominal cavities are rarely suitable for operation; for instance, the bronchial glands, the mesenteric glands, and the retroperitoneal glands. The locality most frequently invaded by the surgeon is the neck. The operation must be performed with all aseptic care. Primrose prefers carbolic acid as the best form of antiseptic, and thinks there is practically no danger to life in these operations. [The dry dissector of Allis is the best instrument with which to dissect out glands. The constitutional and hygienic treatment of the patient is of the first importance, as Treves emphasizes. (See next article.) Treves has also shown that all tubercular glands do not require excision. (See next article.) If excision is employed, it must be thorough; the deep cervical glands must be removed as well as the superficial glands; the jugular vein must be completely bared from skull to clavicle, and sometimes the sterno-cleido-mastoid must be divided, although this is rarely necessary. If it is divided, it should subsequently be sutured with catgut. In removing lymphatic tuberculosis the surgeon must be careful not to cut the 7th nerve. Spengel has in 2 cases extirpated the pelvic glands for tuberculosis. The inunction of guaiacol is of great value in many cases of local tuberculosis.]

Treves[3] presents in his well-known emphatic style **the surgical aspect of tuberculosis.** He tells us that it was assumed less than 50 years ago that tuberculosis was beyond the province of the surgeon. The surgeon was permitted to take a languid interest in the disorder called scrofula, although his powers for good did not extend beyond the application of iodin with a paint brush. The laying on of iodin served to replace the laying on of hands which had previously given the kings the privilege of curing this affection. Scrofula was a very convenient disorder, being the cloak to cover a multitude

[1] Univ. Med. Mag., Oct., 1895.

[2] Canad. Pract., Dec., 1895.

[3] Lancet, Oct. 26, 1895.

of pathologic sins. It represented something in the blood; it had a whispered kinship to syphilis. There was about it something of the attractive romance which attaches to an obscure domestic scandal. It was like the x of algebra, representing a profound quantity of ignorance. Since the term tubercular crept into existence scrofula and tuberculosis began to play the part of two Dromios in a tedious comedy of errors. Treves then reviews the history of the controversies out of which have come a more accurate knowledge of the relationship of the so-called scrofula and tuberculosis. He discusses the various modes of infection, and then takes up the treatment from a surgical standpoint. He tells us that the first elements in the treatment are fresh air, sunshine, and good food. There are no drugs which are specifics against tubercle, and three-fourths of the medicines given are administered not to treat the disease, but to soothe an inherited craving in the human race for physic, which is almost as uncontrollable as the craving for drink. During the cold weather these patients should take an extra amount of fatty matter in the form of fat, butter, or cream. There is no excuse for the administration of cod-liver oil. There is no more nauseous form of fat to be found, and it does not contain any chemical quality other than that of the oil. It was originally introduced when it was considered in keeping with the fitness of things that all medicine should be nasty. If adults like this oil, by all means let them take it, but it is unkind to force it on children, who have no prejudices as to the efficacy of medicine and have not reached an age to appreciate the beauty in nastiness. The public clings to the belief that there are such medicines as tonics. Tonics are medicines which are supposed to give an individual strength. It is needless to say that no medicine can effect this. Strength cannot be poured down the esophagus. One might as well add to the Pharmacopeia a physic the taking of which will give wealth. When there is anemia, iron ought to be administered. Arsenic and quinin are occasionally of value, and in some few instances potassium iodid is of service. When we come to the consideration of special joints, the first necessity is to place the patient under the best hygienic conditions possible and maintain the joint at rest. In hip-joint disease the thigh is not to be suddenly forced into a stereotyped position which the surgeon insists is one of rest, but which the patient knows is one of discomfort. The limb is to be gently induced into the natural position and kept there. Under the treatment of perfect rest the majority of cases of tuberculous joint disease recover. If an abscess forms in connection with the hip, and that abscess be treated upon general surgical principles, it will, as a rule, get well. A view not many years ago was maintained that as soon as an abscess appeared excision ought to be carried out. Treves dissents from this opinion. He tells us that even the excellent operation of arthrectomy, for the elaboration of which surgery is chiefly indebted to Mr. Wright of Manchester, is becoming wisely restricted in its use.

The treatment of tuberculous glands of a certain grade by complete excision is in every way excellent, but surgeons occasionally tend to run into extremes. Some few assume that excision is the only treatment for tubercular

glands, asserting that there is no other course open and that disaster will follow any delay in operation. This is pressing an admirable measure to an extreme and irrational use. Certain cases will recover, and recover thoroughly, without operation, and certain other cases are not suited for operation. In the treatment of gland diseases two matters call for early attention. The periphery should be examined and any exciting cause be dealt with. For instance, in cervical adenitis we should look for eczema of the scalp, discharges of the ear, nasal catarrh and enlarged tonsils, postnasal growths, buccal ulceration, or carious teeth. It will be of little avail to treat tuberculous glands until these peripheral conditions are cured.

As a second element in treatment the part must be kept at rest. This is usually insisted upon when the enlarged glands occupy axillary or glands of the groin, but it is very seldom urged in the neck. Yet the neck is in almost constant movement, the glands, the sterno-mastoid muscle, are subjected to continual disturbance; until the neck is fixed the great essential in treatment is ignored. In many cases the diseased glands must be removed. It will not do to be too certain that a removal will leave a fine and invisible cicatrix. Surgeons have become less radical in the treatment of tuberculous testes. The patient should be placed under as favorable conditions as possible, and when softening appears in the epididymis the parts should be incised, scraped, and packed with iodoform-gauze. The operation may have to be repeated several times, but is frequently followed by complete cure. In psoas abscess the incision should be made in the loin. Treves suggested this incision in 1884. The abscess is thus opened as near as possible to the seat of the disease. The spine can be examined over a limited area, and sometimes diseased bone can be removed. When the abscess has been evacuated sharp spoons are introduced and the lining wall of the cavity is thoroughly scraped. During this scraping the cavity is frequently flushed out with warm sterilized water. The finger is used to break down septa and to open up diverticula. When the cavity is clean it is dried with Turkish sponges on holders. A little iodoform emulsion is injected and the wound closed. In spite of contradictory reports from laboratories, clinical observation seems to render it certain that iodoform has a specific effect upon tuberculous lesions. The well-to-do patient passes his convalescence upon a spinal carriage in the open air, be it winter or summer.

In discussing tuberculous peritonitis the author tells us that in a series of 308 cases treated by celiotomy there were 74 deaths, but the mortality due directly to the operation was only 2.5%. Those cases did best in which the operation consisted of little more than free incision and in which there was neither flushing nor drainage.

AMPUTATIONS.

Page[1] presents the **results of major amputations** which were treated antiseptically in the Royal Infirmary, Newcastle-upon-Tyne, during the year

[1] Lancet, Mar. 21, 1896.

1895 and for a period of 17 years and 9 months. During 1895, 68 major amputations were performed upon 66 patients; 64 recovered and 2 died, a mortality of only 3%; 23 amputations were for injury; in 1 case a man lost a thigh and a leg; in 1 a child lost a foot and arm and a large part of the other hand. Of the 23 patients, 1 only died, a mortality of 4.3%. Amputation was resorted to 43 times for disease, and 1 died, a mortality of 2.3%. One of the deaths arose from blood-poisoning, but the patient had blood-poisoning when admitted, and amputation failed to save her life. One case of hip-joint amputation died from shock. In each operation, during the performance of the double amputations, hot saline solutions were introduced. Both these patients recovered, and life was apparently saved in each case by the transfusion. In 1 other instance transfusion was resorted to during amputation at the hip-joint. This case also recovered. From Jan. 1, 1883, to Dec. 31, 1895, 778 amputations were done, with 63 deaths, a mortality of 8%; 300 of the amputations were for injury, and 36 died, a mortality of 12%; 478 were for disease, and 27 died, a mortality of 5.6%. Of the 68 deaths which have ensued upon amputation during the last 13 years, 30 have arisen from shock and loss of blood. During 1895 transfusion was resorted to as a means of counteracting the effects of shock and loss of blood, and in every case the effect was very striking. Blood-poisoning as the cause of death after amputation has almost ceased to occur. Page believes that the injection of a hot saline solution into the veins will prevent death from shock and loss of blood in many cases, and that, in fact, the mortality of amputation will be further reduced. From Apr. 1, 1878, to Dec. 31, 1895, 938 major amputations were performed, and 80 patients died, a mortality of 8.5%. The mortality after amputations for injury was 13.1%, and for amputations for disease was 5.5%. [These results are admirable. MacCormac estimated the mortality in the London hospitals at 12.8%. Erdmann considered the results obtained in the hospitals of New York City, and estimated the mortality at 15.5%. Saline transfusion is of great benefit. In a condition where great shock is anticipated the tube should be inserted into

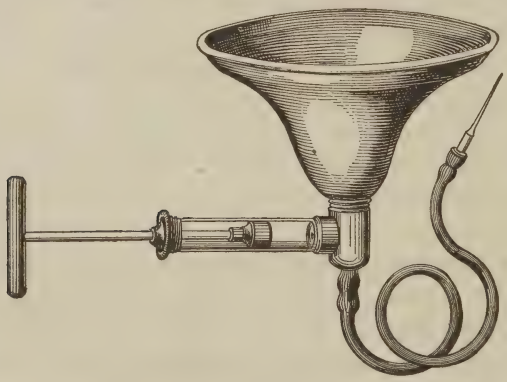

FIG. 8.—Collin's apparatus for the transfusion of blood.

the median basilic vein before beginning the amputation, so that the saline fluid can be introduced at a moment's notice. Great care is employed to allow no air to enter. Keen employs an apparatus (Fig. 8) which renders the entrance of air impossible.]

Wyeth[1] debates the question of **how to amputate.** He says the first question to bear in mind is the preservation of life; the second is the preservation of the greatest amount of usefulness with the portion of the part which is left. Since hemorrhage is the chief factor of shock, the prevention of blood loss is essential. When hemorrhage has not occurred before the surgeon takes charge of the case, this element of danger may be eliminated. When extensive bleeding has occurred before operation, the venous transfusion of a hot saline solution greatly limits the danger of shock and hemorrhage. Wyeth never follows any fixed rules as to how to amputate. He makes the flaps with the end in view of saving as much of the limb as possible. He usually considers the tarsus and the metatarsus as a single bone, pays no attention to joints, takes only the precaution of removing any thin film of bone or cartilage which might remain when the saw passed very close to one of the articulations. He makes one exception to this rule; that is, in amputating at or near the ankle-joint. He is convinced that a more useful member can be obtained by an artificial foot when applied to the stump of a Syme amputation than when applied to the stump of either a Pirogoff or Hancock amputation. From the ankle to the hip the same conservative idea prevails, unless the saw line would pass within an inch of the knee-joint or above the trochanters. In these conditions it is better to amputate at the joint. In amputating the attempt should be made to preserve as much of the extremity and as much of the tactile sense as possible. This is especially true in the case of those employing the hand in any vocation. In certain cases of those who do not labor it may be justifiable to secure a more shapely hand by the sacrifice of more of the members. In endeavoring to prevent blood loss in amputation it is not always necessary to force all the blood out of the extremity. When the patient possesses a normal amount of blood, and there has been no excessive hemorrhage and the general condition of the individual is good, the sudden forcing of a large amount of blood from the extremity into the general circulation may put a strain upon the heart that will produce a fatal result. Out of 7 hip-joint operations which Wyeth has performed by his method he has lost 1 case, and he is persuaded that this death resulted by strain on the heart-muscles due to forcing a large amount of blood into the remaining vessels of the body. Mere elevation of the extremity will cause most of the blood to gravitate into the vessels of the trunk. When a rubber tourniquet is applied to the thigh a wide rubber band should be used, and not a rubber tube, since the pressure of the tube may injure the nerve and may cause paralysis by inciting traumatic neuritis. Of course in amputations at the shoulder- or hip-joint this objection does not prevail, since pressure on the nerve has now become immaterial.

[1] N. Y. Med. Jour., Nov. 16, 1895.

Wyeth presents another point which is a great aid in effecting a rapid amputation. When making a hip-joint amputation or an amputation through large masses of muscular tissue, after tying large arteries and in order not to lose the time that would be spent if forceps were applied to oozing surfaces, pass deep catgut sutures through masses of muscle all the way across the whole cut surface and tie them firmly. Compression so applied prevents bleeding, and 10 or 15 minutes can be saved in an ordinary amputation. In amputating the hip-joint he now employs the tourniquet higher than he once advised. Complete control of the hemorrhage can be obtained by carrying the strong hard-rubber tubing close in the crotch, where it is held by the inner pin. The other pin is inserted so that the tube passes in the notch just below the anterior superior iliac spine. This mode of application brings the pressure above the level of the hip-joint, and the capsule can be opened to the bone, and the bone disarticulated with great rapidity. In some cases there will be found slight dripping from the posterior part of the flap when the bone is removed, but this is immaterial, and can be at once controlled by pressure with the fingers and the application of artery forceps. Amputation for malignant disease should be performed as far from the lesion as possible. [Many surgeons empty the limb of blood by the influence of gravity alone, and never employ the rubber bandage. Lister follows this method, and so does Senn. The suggestion that death may occur from forcing a great amount of blood from a large extremity into the remaining vessels of the body seems highly probable. The reason why it is not advisable to remove the head of the metacarpal bone after amputating a workingman's finger is because the necessary detachment of the transverse ligaments greatly weakens the hand. If a surgeon removes the metacarpal head, he secures shapeliness at the expense of power—a poor exchange which the modern world is rather prone to desire. The treatment of osteomyelitis demanding amputation, as set forth by Wyeth, we know to be efficient by repeated experiences. In Syme's amputation the elder Gross was accustomed to make an oblique incision, but he made it obliquely forward and not obliquely backward. Syme himself carried the incision *straight across* the sole of the foot, unless the heel was very prominent, when he carried it slightly backward. Joseph Bell's Manual of Surgical Operations contains an excellent description of the amputation devised by Syme.]

Samfirescou[1] presents **a new method of amputating at the elbow and the wrist.** A piece of bone is left in the flap, and he speaks of these procedures as osteoplastic amputations. He denominates the elbow operation the "osteoplastic brachioolecranon amputation." A posterior flap is made by drawing an incision from condyle to condyle, 2 fingers' breadths down upon the olecranon process. This incision reaches to the bone, and the soft parts with the periosteum are lifted up to the base of the olecranon. A saw is now taken and a transverse cut is made into, but not through, the bone (Fig. 9). An anterior flap is now cut similar to the posterior one (Fig. 10). The lateral

[1] Rev. de Chir., 1895, p. 839.

ligaments and the anterior ligaments of the joint are incised, the attachment of the triceps muscle is removed from the olecranon to the distance of $\frac{1}{3}$ in.,

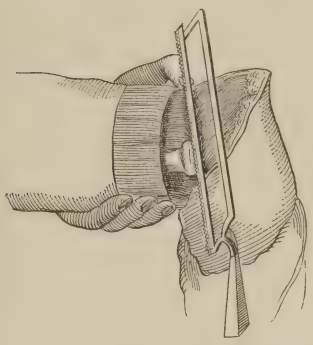

FIG. 9.—Formation and section of posterior flap, and transverse section of olecranon at its base (Samfirescou, in Rev. de Chir., 1895).

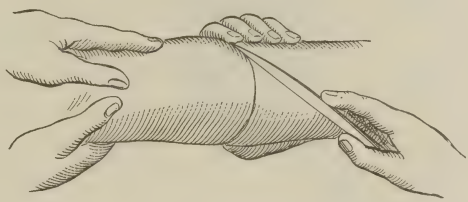

FIG. 10.—Formation and section of the anterior flap (Samfirescou, in Rev. de Chir., 1895).

and the olecranon is opened in the longitudinal direction until the transverse cut which was made at first is reached (Fig. 11). The forearm is now removed,

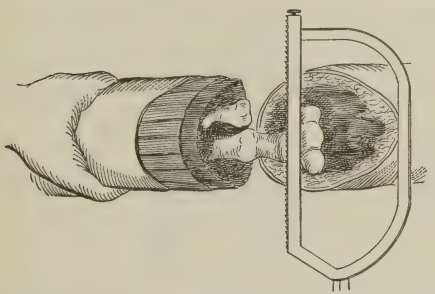

FIG. 11.—Vertical section of the olecranon at the point of junction with the transverse section (Samfirescou, in Rev. de Chir., 1895).

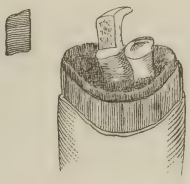

FIG. 12.—The forearm with the other half of the olecranon, the segment of the olecranon remaining in the external flap (Samfirescou, in Rev. de Chir., 1895).

and a piece of the olecranon process remains attached to the triceps tendon (Fig. 12). The end of the humerus is sawn (Fig. 13), and the remainder of the

olecranon is brought against the sawn surface of the humerus and sutured to it (Figs. 14 and 15). The flaps are then closed. The operation at the wrist

he denominates the osteoplastic metacarporadio-cubital operation. He cuts a long external flap from the dorsum of the thumb (Fig. 16), which flap con-

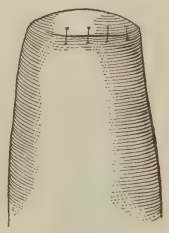

FIG. 20.—The stump (Samfirescou, in Rev. de Chir., 1895).

carpal bone is sutured to the radius and the ulna. The soft parts are then approximated (Figs. 19 and 20). [Samfirescou's amputation at the elbow seems to be upon the same principle as that of Symanowsky. Sabanejeff of

Odessa did a like operation at the knee. Kocher tells us that Sabanejeff sawed horizontally through the broadest part of the condyles and applied to the same surface a flap of bone removed from the anterior surface of the upper end of the tibia. Gritti cut the ligament of the patella, and directs that the articular surface of the patella be sawn off and applied to the sawn femur. (See Theodor Kocher's Text-Book of Operative Surgery.)]

McBurney[1] presents a record of a case in which he had performed **amputation of the forearm** by a new method for the cure of sarcoma of the radius. The ulna was free from the disease and the tumor had a firm capsule. A vertical incision was begun at the elbow joint, carried downward over the radius to the middle of the forearm, and then converted into a circular about the forearm. The flaps of muscle and skin were dissected up. The entire radius was excised; the ulna was sawn below the insertion of the pronator radii teres; the biceps tendon, which had been dissected from the radius, was sewn with catgut to the base of the coronoid process of the ulna. This last procedure was carried out in the hope that the power of flexion would be strengthened. The case resulted well. The patient made a good recovery, the disease has been sufficiently radically removed, the biceps seems to perform its function, the power of flexion is excellent, and the limb is very much more useful than if amputation at the elbow joint had been carried out.

Ritschl[2] records a case in which he did a double **amputation of the leg** with plastic formation of the foot by Bier's method. The patient made a good recovery, 3 months later was provided with boots like those used after Pirogoff's operation, and was able to walk about very well with the aid of a cane. This operation he considers has the advantages claimed for it by Bier —namely, 1. Atrophy from bone and muscle does not take place; 2. The patient has a steady gait, which can be improved by practice; 3. Freedom from ulcers about the head of the tibia; 4. There is no danger of a conical stump; 5. The expense of artificial legs is much greater than the expense of the shoes. [Bier advises amputation through the lower portion of the leg, the making of a cuneiform osteotomy upon the tibia above the stump, the bending forward of the stump with the lower fragment of bone to a right angle with the upper fragment. The two fragments unite and form a foot. (See Kocher's Op. Surg.)]

Rioblanc[3] shows the records of 85 cases of **Gritti's amputation.** They show a mortality of 19%, but not one of these deaths depends in any way upon the mode of operation which was selected. In 69 cases the patella was displaced 7 times, and in 2 of these it was readily restored to position. Suppuration was the usual cause of displacement of the patella. In all cases in which it was possible to watch the patient for a considerable time it was found that the stump stood pressure excellently, and the rule was followed to allow the artificial limb to press directly upon it. He advises the following points as important to remember: 1. Saw the femur 6 or 7 cm. above the articula-

[1] Ann. of Surg., Feb., 1896. [2] Beiträge z. klin. Chir., Bd. xiii. Ht.
[3] Lyon méd., Apr. 21, 1895.

tion. This enables us to easily turn the patella under without cutting the quadriceps. 2. Suture the patella with silk or catgut. 3. Do not use needles or wire. These latter agents might produce rarefying osteitis. Absolutely immobilize the stump and hip-joint for 6 weeks, in order to get solid bony union. 4. Rigid asepsis. [Disarticulation at the knee-joint was preferable, in former times, to amputation through the condyles of the femur, but since the advent of aseptic methods it is not so necessary to amputate as low as possible. An objection to Gritti's amputation has always been found in the trouble the surgeon meets with in turning the patella under. Rioblanc claims to do away with this objection by sawing the femur 6 or 7 cm. above the articulation. He can then turn the patella under without cutting the quadriceps. Gritti's amputation has never become very popular, although it has been before the profession for almost 40 years. It was introduced by Gritti of Milan in 1857. It is difficult to saw the patella, and it is hard to keep it in its new position. Nevertheless, the flap bears pressure well, and the operation, though not as valuable as disarticulation through the knee-joint, is probably better than amputation through the femur above the condyles. Treves gives a very judicious estimate of these condylar operations, and prefers Carden's as the best.[1] Stokes has maintained that in Gritti's operation the patella will not fit in its new position: the sawn surface of the femur is too large, and the patella projects forward or is drawn up in front of the femur. Stokes gets a surface to which the patella adjusts itself by sawing the femur ½ in. *above* the condyles. Lister praises Carden's amputation. Jacobson[2] thinks Carden's amputation a very valuable method.]

Buechner[3] advises that in many cases **amputation at the knee-joint** should be done by the method of Sabanejeff of Odessa. He considers that the stump formed by this operation is as round as the normal knee, and bears the weight of the body without discomfort. The normal relation of the parts is but little disturbed, and the weight is thrown upon a part which is accustomed to bear it and which is arranged for that purpose. It will be recalled that when we kneel the weight does not rest upon the skin covering the patella, but upon that over the tuberosity of the tibia, and this operation enables the sufferer to have the weight upon the proper point. He alludes to Koch's 5 cases operated upon at Dorpat with invariably good results. Buechner gives an excellent description of Sabanejeff's amputation, and says he has employed it in 1 case and is delighted with it.

Miller[4] maintains that **the circular method of amputation** is the one **best adapted to disarticulation at the knee and elbow.** A circular incision is made below the condyles, 1½ in. below them in the arm, 2½ in. below them in the leg. This incision reaches to the deep fascia. The unequal retraction of the skin on the flexor aspect of the limbs makes the line of incision oblique. Two incisions are now made immediately below the condyles and the original cut. This permits the flexor flap to retract still more,

[1] Treves's Manual of Operative Surgery.
[2] Surgical Operations, by W. H. A. Jacobson.
[3] Jour. Am. Med. Assoc., Mar. 21, 1896.
[4] Edinb. Med. Jour., July, 1895.

and a few touches of the knife will cause it to almost entirely disappear. The extensor flap is now dissected up to above the olecranon in the arm and above the head of the tibia in the leg. Disarticulation is performed in front in either extremity. It is well to save the patella when we amputate at the knee. This method gives us a long flap from the extensor surface of the limb, with practically no flap on the flexor surface. It gives a very useful and shapely stump. This method, he maintains, has the acknowledged advantages of a single skin flap, and disarticulation can be very easily and quickly performed. It presents no intricate details. The flap is already accustomed to pressure, but a small amount of tissue is demanded, and the cicatrix is placed in a very advantageous position. [The oblique incision of Kocher possesses all of the advantages of Miller's operation, and is certain to secure an ample flap.]

Ochsner[1] presents a second case in which he operated for enchondrosarcoma by the **removal of the entire upper extremity.** In operating he followed chiefly the rules laid down by Berger. He made an incision over the clavicle, lifted up the periosteum, cut the clavicle with bone forceps, elevated the outer portion, lifted the posterior layer of the periosteum along with the subclavian muscle, and was able to see plainly the vein at the point in front of the middle scalene muscle. The branchial plexus was separated by blunt dissection. The catgut ligature was passed around the artery and vein, and silkworm-gut ligature was passed around the vessels $\frac{1}{4}$ in. above the catgut ligature; both ligatures were carefully tied, forceps were applied to the vessels 1 in. below the ligatures, and the vessels were cut between the forceps and the ligatures. The flaps were formed by Berger's method. There was almost no blood lost during the operation. The author has noticed in a considerable number of amputations near the shoulder and hip that a patient shows little evidence of shock when large nerves are severed with a sharp knife, but shows severe shock when they are cut with scissors. In his former case he ligated the vessels with silk, and as a consequence a sinus formed several months after. In this case he used catgut and applied a second ligature of silkworm gut, which was left long so it could be withdrawn in case the vessel necrosed below the ligature; as this condition did not occur, the silkworm ligature was cut through after the wound was entirely healed. He maintains that it is wise to apply the first ligature around both artery and vein, including sufficient surrounding tissue to avoid the danger of wounding the vein. He does not approve of ligaturing the vessels separately. He believes that this operation is indicated in cases in which sarcoma involves the tissues overlying the shoulder joint, the clavicle, the scapula, or the upper end of the humerus. Because of the well-known tendency of sarcoma of any portion of the humerus to recur, he considers this operation to be proper even when sarcoma affects the lower portion of the bone.

G. C. Hall[2] has reported a successful case of removal of the entire upper extremity. He began by making a posterior flap, and secured the vessels as

[1] Ann. of Surg., Dec., 1895. [2] Lancet, Feb. 8, 1896.

he advanced. He then attacked the part and tied the subclavian artery. The patient made a rapid recovery.]

Charlot[1] advises a method of **hip-joint amputation** by means of which he claims that the danger of hemorrhage can be entirely obviated. He makes a very small incision through the abdominal muscles just internal to the anterior superior iliac spine. He strips up the peritoneum and tissues internally, and passes a finger as far as the angle which the psoas muscle forms with the promontory of the sacrum. There he finds and compresses the termination of the common iliac artery. Of course the upper end of the femoral vein may bleed from reflux, even when the common iliac vein is compressed at the same time as the artery. He carried out this plan in 1 case and found it very easy. [Wyeth's pins are easily used, are secure, permit of firm compression, and never get tired. Finger-pressure is not secure, and is liable to relaxation from tire or from accidental movements. We can see no reason why the pins should not be employed.]

F. Tilden Brown presents, in the Annals of Surgery, a method of **hip-joint amputation** whose special feature consists in controlling hemorrhage **by means of a large-sized clamp.** He makes an anterior incision like that Barker makes for resecting the hip. It is carried down vertically upon the thigh, and a circular incision is made at the lower end of the vertical incision. A clamp is passed in to the vertical cut in such a way as to grasp, without especially compressing, the sartorius muscle, and the ends of the clamp compress the femoral artery and vein (Figs. 21 and 22). Brown claims that this method may be used upon all cases, but is especially valuable

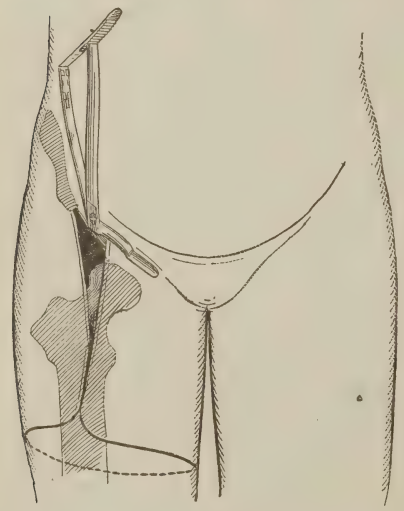

FIG. 21.—To show the anteroexternal incision with its relation to the upper extremity of the femur and to the femoral clamp (F. Tilden Brown, in Ann. of Surg.).

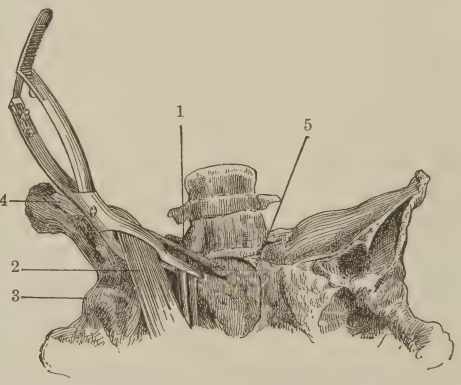

FIG. 22.—Showing application of clamp to the femoral vessels: 1. Poupart's ligament, femoral vessels below it grasped by the clamp. 2. Sartorius straddled and retracted by the clamp. 3. Hip-joint well exposed by inward retraction of sartorius. 4. Origin of sartorius at the anterior superior spinous process. 5. Symphysis (F. Tilden Brown, in Ann. of Surg.).

where the operation was begun as an exploratory incision, incision disclosing

[1] Ann. of Surg., Sept., 1895.

the fact that amputation is necessary. Brown says if he were deprived of the services of the clamps he would use digital compression of the femoral vessels immediately below Poupart's ligament, the fore finger being passed through the upper angle of the incision and under the sartorius muscle to beneath the common sheath of the artery and vein. [The clamp is more troublesome than the pins. The operation must be prolonged, and all other vessels except the femoral will bleed. The anterior incision can be made if the pins are applied high up.]

Paul [1] reports 7 cases of **hip-joint amputation** without a single death. Since hip-joint amputation can be performed with as great rapidity as any other major operation, and as it involves but little more tissue, he thinks the usual high mortality is due to hemorrhage. He fixes Esmarch's band by a bandage passed over the shoulder and around the opposite hip. He cuts a large anterior flap, disarticulates, and cuts through the posterior flap from the wound outward. As soon as the anterior flap is cut the femoral artery is tied. The strips of bandage which hold the tourniquet are 2 in number, 1 in front and 1 behind, and they are carried around the pelvis above the crest of the ilium in front and the tuberosity of the ischium behind; then the ends of the bandage are taken back to the shoulder and hip and tied tightly. As this maneuver takes off some of the compression of the band upon the iliac artery, a roller bandage ought to be pushed under this tourniquet at this spot to increase pressure on the artery.

In a note the author also tells of an 8th case which was also successful. [These statistics are most gratifying. This mode of arresting hemorrhage is valuable in an emergency, but is not as secure as the method of Wyeth. The fact that lifting the band toward the body "takes off some of the pressure" constitutes an objection to the plan.]

ANESTHESIA AND ANESTHETICS.

Scofone and Battistini [2] have made experiments with **formanilid** and **antipyrin** as anesthetics. They conclude that formanilid in solution of a strength of 2% and antipyrin in a solution of 30 to 50% can produce local anesthesia when applied to the mucous membranes, to skin from which the epidermis has been removed, to the trunks of nerves, to muscles, and to the brain. Washing off the part with a normal salt solution quickly arrests the anesthesia. Formanilid is not altogether safe, as it may produce poisonous symptoms. [The anilids are "substituted anilins with acid groups in side chain" (Sadtler and Trimble). They can be made by treating anilins with acid chlorids or acid anhydrids. Formanilid is made by rapidly distilling anilin with oxalic acid. It appears as colorless crystals soluble in water or alcohol. Acetanilid belongs to the same group as formanilid. Antipyrin in solution of only 10% has more anesthetic effect upon mucous surfaces.]

Lucas Championnière [3] has made extended trial of **guaiacol** as a local

[1] Liverpool Med.-Chir. Jour., No. 29, 1895. [2] Wien. med. Presse, 1895, xxxvi. p. 1338.
[3] Bull. de l'Acad. de Méd., July 30, 1895.

anesthetic. This drug was first applied to relieve pain by Andre, a Parisian pharmacist, who applied it to a burn on his own person. The results of this were most gratifying. The drug was then tried hypodermically. Sterilized solutions of guaiacol and oil of sweet almonds were used, but guaiacol was subsequently found to be a better menstruum than the oil of sweet almonds. Solutions of the strength of 10% and 5% are used in the 1% solutions; 10 cgm. of guaiacol are injected, and in the 5% solution 5 cgm. This method was tried in extracting teeth and was found to be entirely successful. Lucas Championnière has used it in many minor surgical operations. He tells us that it is as powerful as cocain, and is free from the dangerous effects of cocain. After administering the injection the surgeon should wait from 5 to 8 minutes for the drug to completely take effect. [That guaiacol is said to be safer than cocain is worthy of attention, as the latter agent frequently produces alarming symptoms and has caused not a few deaths—more, probably, than have been reported. Bazy urges dentists to try guaiacol, as the dental use of cocain is especially dangerous, because the patient is not recumbent. The same observer says that guaiacol is superior to cocain in the fact that it fully anesthetizes muscular areas. Pine has stated that pain under the skin can be relieved by applying compresses wet with from 15 min. to ʒj of guaiacol and bandaging them firmly in place. Guaiacol applied in this manner produces anesthesia of the skin to such a degree as to permit of the performance of slight operations. Large amounts of the drug or an impure article must not be used, he says; neither must the application be prolonged, because of the danger of collapse. Ferraud says that 1 c.c. should be the amount applied externally—that this amount allays the pain of intercostal neuralgia and phthisis; it may produce abnormal temperature, but is not dangerous. Laborde, Gilbert, and Degan have testified to the anesthetic effects of the drug. The agent is a powerful vaso-constrictor, and Championnière has seen local gangrene follow its use.]

Schleich [1] has presented a new local anesthetic which he calls **eucain.** It is claimed to be as efficient as cocain, and to be free from the dangerous qualities of the latter. The salt used is the hydrochlorate, which is soluble in water and does not decompose when boiled with water. The solution does not subsequently form a precipitate, and it is not necessary to add phenol or salicylic acid to preserve it. This agent is efficient when painted on mucous membranes or when injected into the area to be operated on. It produces a more extensive area of anesthesia than does cocain, and the anesthesia lasts longer. [Trial has been made of eucain in the out-patient surgical department of Jefferson Hospital, and the results have been most satisfactory. In the removal of ingrown toe-nails we have a procedure which brings a local anesthetic to the test, and in these usually painful operations eucain has proved more satisfactory than cocain, the anesthesia from eucain being more profound and prolonged and widespread than is that from cocain. (See Dr. Geo. W. Spencer's report in the Univ. Med. Mag., Nov., 1896.)]

[1] Am. Med.-Surg. Bull., June 6, 1896.

Andre Lapointe[1] maintains that we should never induce **cocain-anesthesia** without strictly observing the following rules, as the safety of the patient demands this care: The solution should be always fresh, not of a greater strength than 1%; a sterilized syringe which holds 15 ♏ is employed to make the injections. The patient should invariably be in the recumbent position, and the surgeon should not wait longer than 5 minutes after injection before beginning operation. More than 2½ gr. of the drug should never be administered. Cases of poisoning, cerebral anemia, and syncope are apt to arise, due to the constricting action of the cocain on the bloodvessels. [In many more cases than is usually assumed some degree of toxic influence is manifested after the use of cocain. The slighter symptoms are dry mouth, repeated attempts at swallowing, dilated pupils, cold extremities, high-tension pulse, which is usually slow, restless tossing, tremor, and talkativeness, followed by a sleepless night and the passage of large amounts of pale urine. The graver symptoms are better known—delirium, syncope, convulsions. Death may be due to paralysis or to fixation of the respiratory muscles (Mosso). The drug is often dangerous, always uncertain, and many people have an idiosyncrasy toward it. Reclus said over a year ago that 14 deaths from it were upon record. Not more than gr. ⅓ should be used hypodermatically.]

Weller Van Hook[2] strongly maintains the value of **infiltration-anesthesia** by the method of Schleich. Schleich found that by combining a small quantity of cocain with a weak salt solution there was no discomfort in the injection, and prolonged anesthesia was produced, and that the addition of a little morphin to the solution prolonged the anesthetic action to a greater degree. Anesthesia which follows such an injection is due to artificial ischemia, the pressure to which the tissues are subjected, the lowered temperature brought about by the cool injection, and finally to the direct action of the contained drugs. As local anesthesia can be induced in a very few minutes with the use of a solution of 1 part of cocain in 1000 of water, this method certainly presents great advantages. The materials required consist of a good ordinary hypodermic syringe and the following solution: 1½ gr. of cocain hydrochlorate, ⅓ gr. of morphin hydrochlorate, and 3 gr. of common salt, which are dissolved in 3 oz. and 3 drams of sterilized water. The surgeon can carry with him in his minor operating case a number of such powders, so that his solution is always fresh. If the solution is several days old, 2 drops of 5% phenol should be added to it before using. Two other solutions are recommended—one containing double the quantity, the other containing $\frac{1}{10}$ the quantity, of cocain of the first solution. The very strong solution is used for inflammatory lesions, the weak solution for prolonged operations. For most cases the medium solution is the best.

Van Hook insists that the value of these materials lies almost entirely in their application. The hypodermic syringe is used to fill the tissues to distention with the fluid. The needle is introduced into the skin at the desired

[1] La Presse méd., 1895, No. 35.

point, the syringe being held almost parallel with the skin. The point of the syringe must not be pushed through the skin, but must stop within the skin,

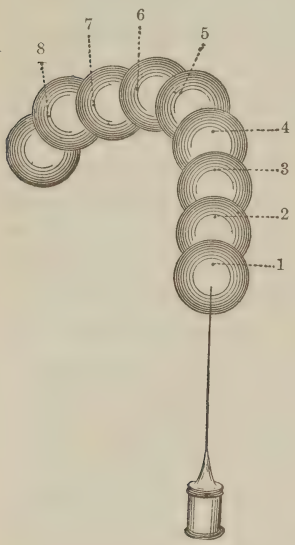

FIG. 23.—Showing how the successive wheals are raised, the point of the syringe being inserted at the points marked by the dots (after Schleich, Med. News, Nov. 16, 1895).

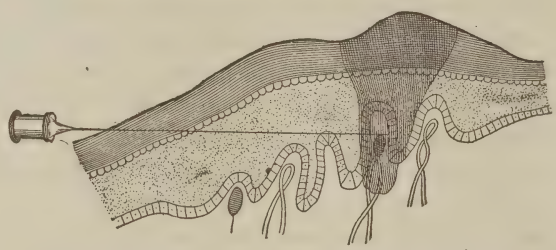

FIG. 24.—The syringe-point stops at the papillary layer, and the fluid lodges in the skin itself (Schleich, Med. News, Nov. 16, 1895).

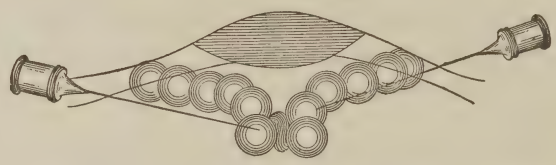

FIG. 25.—Showing mode of injecting the fluid under an abscess (Schleich, Med. News, Nov. 16, 1895).

so that the fluid will distend the skin, thus raising a white wheal somewhat like a mosquito bite (Figs. 23–25).

Schleich himself freezes the skin at the site of the first puncture with the spray, ethyl-chlorid. When the area is infiltrated it becomes instantly anesthetic. The surgeon must be sure the area he wishes to operate upon is thoroughly infiltrated, and when pain is produced in operation it is because the surgeon has not infiltrated thoroughly. When the first small area has been anesthetized it only remains to infiltrate a sufficient number of new circles adjoining the first to include the field of operation, and as the first area is devoid of sensibility the adjacent skin can be infiltrated by painlessly inserting the needle into the edge of the wheal and forcing the fluid into the tissues met at this point.

Having anesthetized the skin area at this point, the subcutaneous tissue is infiltrated by passing the needle through the skin. The fascia, muscles, and periosteum can be anesthetized in the same way. All these procedures may be carried out aseptically. The anesthetic influence lasts about 20 minutes. If the operation is longer than this, the infiltration can be repeated.

We should remember that inflamed tissues are hypersensitive, and must not themselves be infiltrated until the neighboring tissues have been anesthetized. For instance, we should never inject the fluid into the apex of a furuncle without first anesthetizing the skin around it. When working on the skin and mucous membrane the surgeon should use fine and sharp needles.

If it is necessary to sever large nerve trunks, inject first a drop or two of 5% phenol into the sheath of the nerve. In amputating fingers begin the infiltration over two points on opposite sides of the member and continue it along the line of proposed incision, and infiltrate the deeper tissues, including the periosteum, with great care. The most serious case on which Van Hook has operated by this method was a varicocele. Schleich has performed celiotomy under infiltration-anesthesia, removing ovaries, tubes, etc. Van Hook holds that we should use this method in opening an appendicular abscess when the abscess is adherent to the abdominal walls and requires simple drainage. Local anesthesia is especially desirable in opening and draining empyema cavities, since when the thoracic viscera are compressed even ether is very dangerous.

The recent advances in the methods of **local anesthesia** is the title of a paper by Lund[1] of the Boston City Hospital. He clearly and carefully reviews the recent progress which has been made, and describes especially the **infiltration-method of Schleich.** He insists upon the necessity for a careful technic, and maintains that the anesthetic effects of the fluid are greatly enhanced by keeping the bottle on ice before operation. He tells us that to Schleich is due the credit of demonstrating that the intracutaneous injection of various drugs, and not cocain alone, in very dilute solution produces local anesthesia, the effect not depending solely upon the drug itself, but being due to the pressure of the infiltrating fluid upon the nerve filaments, the arterial anemia, and the comparatively low temperature of the fluid. These facts enable us to dispense with cocain except in proportions so small as to relieve us of any apprehensions of danger. The injections are begun endermically, and not hypodermically, in the healthy skin surrounding the inflamed area, and the latter is advanced upon carefully and is gradually and thoroughly infiltrated. The area of infiltration must not only go around, but must get beneath, the inflamed tissues, so as to completely encompass them with an area of artificial edema. In infiltrating the wall of an abscess remember that injections into the abscess-cavity will do no good. If there is no outlet, they add to the pain by increasing tension. If there is an outlet, they run out without infiltrating the tissues. Injections into the sacs of cysts or the tissues of tumors are barren of all results. Every tissue of the body is rendered anesthetic when infiltrated in the manner described, and we can even anesthetize bone by infiltrating the periosteum or by injecting the medulla. Nerve-trunks are anesthetized first by touching the spot with a drop of pure phenol, and through this making the injections in the same manner that we anesthetize mucous membranes. When operating under the influence of this method there will be very little bleeding, because the distention of the tissues compresses the small bloodvessels. If it becomes necessary to grasp a divided artery with forceps, touch it first with a little pure phenol, in order to anesthetize the nerve which accompanies it. Lund does not think that the method is suitable to extensive operations in inflamed and brawny

[1] Boston M. and S. Jour., Feb. 6, 1896.

tissues, owing to the mechanic difficulty of thoroughly and painlessly infiltrating all the inflamed area. This is especially true when the inflamed tissues are brawny or are richly interwoven with fascial fibers. Abscesses of the palm of the hand and sole of the foot in laboring men are not suited to this method, although it is quite true that a soft and pliable palm can be infiltrated with success. The method is very successful when applied to loose and spongy tissues, even if they are much inflamed. Felons can be opened and curetted, sequestra removed, and amputations performed with absolute freedom from pain. In the performance of more extensive operations the surgeon must be ready to lay down the knife and take up the syringe on the slightest expression of pain by the patient. In some very nervous patients the method is difficult to apply, and such people will do better under ether. The general verdict will be against Schleich's method in major operations. It is not wise to complicate difficult operations by constantly stopping to reinfiltrate the operative field, and it is not always desirable to have the patient witness the efforts of the surgeon even though they be painless. In cases, however, where the condition of the heart, shock, or the danger from vomiting (for example, in strangulated hernia) render ether dangerous, the infiltration-method is of immense advantage. There is no reason why such operations as kelotomy for strangulated hernia, tracheotomy, resection of a rib for empyema cannot be performed under infiltration-anesthesia. The advantage of general anesthesia in long and complicated operations, even in short operations where muscular relaxation is desired—for instance, the reduction of dislocations or deformities due to fracture—are so great that we do not think it will ever be displaced by the infiltration-method.

J. Jackson Clarke[1] makes some observations upon **cocain-anesthesia,** which he strongly approves of in minor surgery. He thinks the more serious operations are unsuited for cocain-anesthesia, because unexpected complications may arise and demand very radical measures, but in emergency cases cocain may be used, especially in tracheotomy Whenever we can apply an elastic band we can use cocain with far more safety than in regions where this cannot be done. He has observed in 1 instance deafness and nausea follow the hypodermic injection of $\frac{1}{10}$ gr. Old people are especially susceptible to cocain, and whenever it is used amyl-nitrite and brandy ought to be readily accessible. In heart-disease the drug is not safe. Most fatal accidents have been due to the application of cocain to mucous surfaces. It is undoubted that many cases attributed to special idiosyncrasy have arisen because the drug was thrown directly into the veins or because an inordinate dose was administered. For a number of years Clarke has been using a 1% solution for hypodermic injections and a 2% solution for mucous surfaces, but of late he has accepted the Schleich method. He then discusses the Schleich method, and agrees in the main with what we have previously stated. He tells us there is a limit to the amount of infiltration which is desirable, for if the wheal is extremely tense the parts will remain red and tender for 24 hours after the injection. He does

[1] Lancet, Jan. 18, 1896.

not think that we possess a perfect syringe. [Bransford Lewis has modified the needles and devised a syringe for infiltration. With ordinary needles there is always danger when injecting the deeper structures, that of puncturing some large vessel. This is to be especially apprehended in the enucleation of glands from over the femoral vessels.]

Lewis's needles are shown in the cut (Fig. 26). They are blunt and are

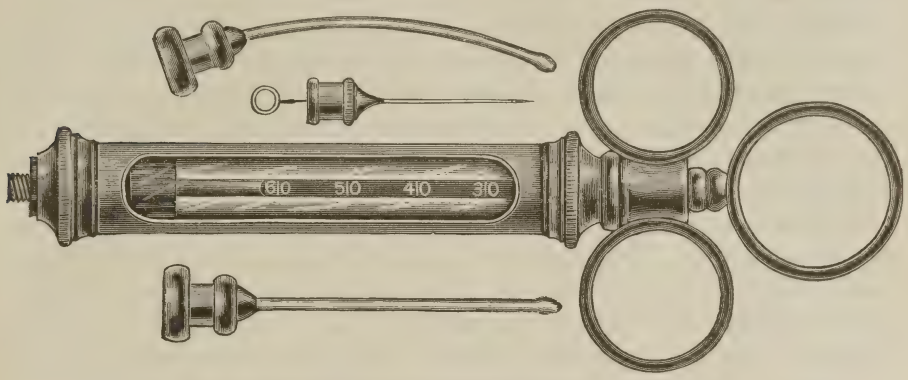

FIG. 26.—Lewis's needles and syringe for infiltration-anesthesia.

made of German silver. They are strong enough to be pushed into connective tissue after the skin has been cut, but are not strong enough to be pushed into a vessel, as they will bend rather than penetrate. Anesthesia is begun in the superficial parts by the use of sharp needles of steel, and is continued in the deeper parts by the use of blunt needles of German silver. (See Va. Med. Monthly, Feb., 1896.)

[For generations surgeons have sought to secure local anesthesia. It was known centuries ago that the local application of carbon dioxid had some power to allay pain, and the celebrated Memphis stone was esteemed because it furnished a ready means of generating this gas. The yeast poultice of our fathers was a local sedative because of its power to give off CO_2. Near the end of the last century Moore tried compression, endeavoring to make pressure upon the nerve trunks and thus produce anesthesia in nerve trajectories, but the method was itself painful, was unsatisfactory, and was not free from danger. James Arnott invented the process of freezing by ice and salt (2 parts to 1 part); B. W. Richardson substituted the ether spray for ice and salt; and Bigelow of Boston commended the use of rhigolene. Freezing has never been satisfactory except in trivial operations. We freeze a larger area than we need to cut. The freezing alters the appearance of the tissues and thus makes exact recognition difficult; it hardens the tissues and renders cutting slow and uncertain; it is only suited to superficial parts; pain is felt during the processes of freezing and thawing, and severe inflammation, even sloughing, may arise in the damaged area. Freezing, however, has a distinct field of usefulness: it is of value when we wish to make superficial incisions or punctures, and is of great use to prevent the pain of the needle puncture in injecting

Schleich's fluid. Ethyl-chlorid is the best agent with which to freeze tissue. It comes in glass tubes which are drawn out to a point; each point is perforated, and is covered with a brass screw-cap. When the cap is removed the ethyl comes through the fine opening when the bulb is held in a horizontal position, and furnishes a spray, and the flow of the spray can be hastened by holding the bulb in the warm palm. In order to freeze a part the tube should be held 9 or 10 in. from the skin. The skin is first reddened, but as it freezes suddenly turns white, and when the skin has whitened the area will remain anesthetic for 10 minutes or more. These tubes of ethyl-chlorid were devised by Bengué of Paris. Schleich was impressed with the unsatisfactory nature of attempts to secure local anesthesia, even cocain having failed to realize expectations, besides being sometimes dangerous. He found that cocain sometimes was satisfactory, but sometimes failed utterly, the failure being due to the fact that the fluid was not widely enough diffused to anesthetize the anastomosing fibers. Leibreich showed us long ago that the injection of water would irritate nerve filaments, and by abolishing their function would produce anesthesia, but this area of anesthesia was itself painful (anesthesia dolorosa). Schleich found that injections of normal salt-solution produced no pain and obtained no anesthesia, because it produced no nerve irritation. He further showed that a $\frac{2}{10}\%$ salt solution produced no pain and obtained anesthesia in normal parts, though not well in inflamed parts. The anesthesia produced by salt solution is due to pressure, to edema, and to slight irritation of nerves, but to obtain it the area must be distended or infiltrated. He found that small quantities of morphin, carbolic acid, and cocain, when added to the fluid, intensified and prolonged the anesthesia and enabled us to obtain it even in inflamed tissues. This is because the large amount of solution brings the cocain and morphin and phenol into intimate contact with nerve filaments over a wide area. The cocain and morphin are present in such small quantities as to cause not even the slightest danger. Schleich's method is not suited to long operations, as the surgeon might be forced to repeat the injections again and again. It is not suited to operations of great danger, as even the bravest patient might move or tremble, and it is not fit that even the bravest should be made to contemplate his danger. It cannot be used when muscular relaxation is sought for. It can be used in a great number of operations, and is an agent of the highest value. Dr. Keen has performed Bassini's and Maydl's operations and tracheotomy with perfect ease under Schleich's anesthesia. Under the same process Schleich has done celiotomy. Tracheotomy and kelotomy can with advantage be done under local anesthesia; so can rib resection, opening of abscesses, amputation of fingers and toes, the removal of many small tumors, and some plastic operations.]

Wurdemann discusses the **infiltration-method.**[1] After setting forth the essential points he cautions us to remember that the use of attenuated solutions of narcotic drugs has nothing akin to homeopathy. Cocain-injections in strengths of 5 to 10% solutions are very much more dangerous to life than

[1] Jour. Am. Med. Assoc., Nov. 16, 1895.

is the inhalation of chloroform. The higher strengths of cocain retard the healing process, and in some cases destroy the trophic nerves and produce gangrene. Schleich's method never causes anything of the sort. The anesthesia from it is very complete and is immediate. We might safely operate by this method for 2 hours if so inclined, repeating the injections whenever pain became manifest.

Freeman of Bristol is a strong believer in the slow and gradual anesthesia. He employs **the Clover inhaler.** He states that in using this inhaler the common custom is to rotate the ether reservoir until the indicator shows full-on, then to get the patient under, and then to let the indicator down to the figure 2 for the rest of the operation. He used to employ this method, but now he finds it easy in 90% of cases to obtain satisfactory anesthesia by rotating the reservoir to the figure 2 until the patient is gotten under ether, and then maintaining the anesthesia with the indicator midway between 1 and 0. This gives the patient less ether and maintains complete anesthesia. There are not the same dangerous reflex symptoms in incomplete ether-anesthesia as in incomplete chloroform-anesthesia, and yet even incomplete ether is more dangerous than complete anesthesia. Occasionally strong muscular men, especially alcoholics, will require more ether than we have indicated. As soon as the breathing becomes stertorous another breath of fresh air should be given—not many breaths, for if we allow this the patient would begin to come to. When complete narcosis has been induced the anesthetist permits sufficient air to enter to prevent cyanosis, and limits the entry sufficiently to prevent the patient coming out of the anesthesia. The longer the patient is under the anesthetic the greater the amount of air we can administer. The quantity of fresh air that should be given after the patient has been under the anesthetic for an hour would be incompatible with good anesthesia in the early stage of the administration. One breath in 8 or 10 inhalations can be permitted after the first 20 minutes, and after that 1 in every 5 or 6. So long as there is no cyanosis, we know that the patient is getting sufficient air, and by using a less concentrated vapor of ether there is less tendency to duskiness than when a strong one is given. It is always better to give ether slowly at the beginning, because by this means the patient's mind becomes dazed before the vapor is sufficiently strong to cause discomfort. When we commence with strong vapor, spasm of the glottis is usual, and this produces a fearful sense of impending suffocation. By this slow method of administration there is less secretion of saliva and mucus, and this is another reason why there is less cyanosis. The air-passages are not much irritated, and accumulation of mucus in the trachea is not likely to take place. The pupil, too, is a smaller one. The after-discomfort is less, the patient comes around quickly, there is less vomiting, and the taste and smell of ether soon pass off, and after-affections of the air-passages are unusual. When administered in this manner ether can be given with perfect safety to children and elderly people. [We have always believed strongly in the slow administration of ether. It is safer; it is more comfortable; it is surgical; it gradually brings about a

change in the blood and tissues, which if brought about suddenly must be dangerous; and anesthesia can usually be obtained without struggling. The rapid administration produces cough, a horrible sense of impending suffocation, fear of death on the patient's part, vomiting, struggling, cyanosis. We know of few spectacles more barbarous than that of a patient being enthusiastically anesthetized by a novice, when ounces of ether are poured upon an inhaler, and a corps of combative and irritable assistants fight and struggle with some unfortunate who believes he is fighting for his life. We have never been persuaded that any of the more complicated inhalers is equal to the device of Allis in safety or simplicity.]

Ziegler,[1] who has recently taken to the administration of **ether,** holds that many of the usually recorded unpleasant effects can be entirely obviated by care and experience in the administration; furthermore, that ether is less dangerous than **chloroform** because cardiac failure, though it may occur, is secondary to respiratory failure, which latter condition gives fair warning and can be successfully overcome. He thinks ether is not advisable in face operations, and is contraindicated in diseases of the air-passages. He says that the latest statistics show that 1 death occurs in 1900 administrations of chloroform, and 1 death in 26,000 cases of administration of ether. [Chloroform is undoubtedly administered with more ease in face operations, but ether can be given if desired. Souchon's apparatus (*Year-Book*, 1896, p. 332) enables us to give ether readily without being in the way of the operator. In operations about the face and mouth many surgeons first anesthetize with ether, and substitute chloroform when the operation begins. Chloroform is given more easily in such cases, because a large admixture of air is beneficial rather than harmful, and the anesthetizer does not employ a bulky towel or inhaler, but simply cotton wrapped in a piece of gauze grasped by a pair of ring-forceps. In regard to the relative death-rate between ether and chloroform, Chaput maintains that chloroform kills 1 in 2000, ether 1 in 13,000. This distinguished surgeon prefers ether for other reasons as well. It is quicker than chloroform, anesthesia being complete in from 4 to 6 minutes; it strengthens the heart; it produces less injury to the kidneys; it rarely causes vomiting; patients revive more quickly; it can be given by a comparatively unskilled anesthetizer, while chloroform can be entrusted only to a skilful man. Poncet has used ether in from 23,000 to 25,000 cases, and has had 1 death. He thinks that the danger of ether is suffocation, and this can often be successfully combated by artificial respiration or tracheotomy (he has performed tracheotomy with success 4 times). He does not use ether in the very old or very young (danger of bronchial catarrh), at night (danger of fire), or about the face; and he never gives morphin and atropin before administering ether, as he considers mixed anesthesia dangerous. We think the danger of using ether at night has been much exaggerated. We use it frequently at night, and simply take the precaution to have ventilation and to see that any light is placed high up and not below the level of the patient's head. In regard to

[1] Münch. med. Woch., No. 23, 1895.

ether being less apt to cause vomiting, we must disagree. Championnière is right when he declares that ether frequently produces after-vomiting, after-excitement, and thirst. (See abstracts by Wilson in Am. Jour. Med. Sci., Feb., 1896.) Chloroform is pleasanter, ether is safer in general. In some particular cases chloroform is safer than ether. It is safer in the aged and very young.]

Gurriere [1] has been repeating the experiments of Dolbeau with the purpose of determining whether **chloroform** could be successfully **administered during sleep** without wakening the sleeper. Dolbeau conducted his experiments on individuals affected with bodily disease. Gurriere performed his upon individuals free from bodily disease who were convalescent from mental troubles at the time of administration. The administration of chloroform was begun very slowly, a handkerchief containing it being held 3 in. from the nostrils and gradually taken nearer to them. If the patient made attempts to wipe away the cloth with the hand, or if any other reflex motions were noticed, the administration was temporarily suspended. The subjects were never told beforehand that the attempt was to be made upon them. Positive results were obtained in 4 cases out of 9. Among the 5 failures 1 was determined to be due to a very light sleep. This patient without his knowledge was given a little morphin some hours before bedtime, and then chloroform-anesthesia was successfully secured. So it is proper to maintain that this result was obtained in 5 cases out of 9. On waking in the morning the patients had no knowledge of waking during the night or that chloroform had been given.

Pettyjohn [2] records a case in which some teeth were successfully transplanted under chloroform-anesthesia applied during sleep. Chloroform was administered without the child awakening. [High authorities have denied the possibility of inducing anesthesia during sleep. That it can be done is proved by the above papers. The *Year-Book* for 1896 cited a case where it was successfully accomplished. The fact is true, but it is of more importance medico-legally than surgically.]

Andrea Ceccherelli [3] has studied the **temperature changes** induced by **chloroform-narcosis.** He states that in anesthesia the temperature is subnormal, but the lowering is not progressively continued to the end of the administration of the anesthetic. The lowering of the temperature oscillates more at the beginning of narcosis than it does at the end. When the temperature touches its lowest point it oscillates about this point, and the more the oscillations are in relation with strong pulse and good respiration the less need there is of apprehending danger to life. Temperature begins to rise when the narcosis is terminated. The longer the narcosis lasted and the lower the temperature, so the longer is the time necessary for the temperature to again reach the normal standard. [Ether also lowers temperature, often as much as 3° to 4° F.]

[1] Rivista Sperimentale di Freniatria, 1895. [2] Med. Rec., June 4, 1896.
[3] Il Policlinico, 1895, No. 17.

Carmichael[1] of the Edinburgh Royal Hospital for Sick Children asserts that **chloroform** is safer **in a child** than in an adult. Children are much more sensitive to it, and a very much smaller dose is necessary to produce unconsciousness. In children we may practically exclude from the risks attending the administration the degeneration of the heart and vascular system, which is the great danger in adults. The action of the drug upon the nervous system of the child is extremely rapid, and this is the element of safety if the administration is conducted carefully. The action is quick, but the reaction is equally quick. Carmichael does not believe in slow anesthesia, but advocates rapid anesthesia. He holds that in the slow method the patient is longer under the influence of the anesthetic, and is therefore for a longer time in danger; time is allowed for the saturation of the blood, and there is less likelihood of a quick reaction. In the slow method of administration there is a prolonged period of excitement, and in this period the risk is greater than it is at later stages. What Carmichael aims at is what Owen calls **the Edinburgh method**—that is, the administration of as little of the anesthetic as will produce rapid and complete narcosis, as evidenced by the abolition of reflexes and muscular excitability. An overdose is a great danger, but the caution in administration which includes previous preparation of the patient and during administration unremitting attention to the respiration, the circulation, and the nervous system, will ensure safety in the great majority of cases. [We stated before our belief in the slow method rather than the rapid method. The rapid method is apt to suddenly overwhelm the system. A man who can slowly drink a pint of whiskey without obvious harm is put in danger of his life if he gulps it all down at one time. If this is true of alcohol by the stomach, why should it not be true of ether or chloroform by the lungs? Slow administration is safe, rapid administration is dangerous. White has shown that the blood of the carotids after an animal has been killed by overdose of chloroform contains only $\frac{2}{3}$ amount of the drug which is present when an animal has been slowly and safely anesthetized. This proves that not the amount but the sudden administration constitutes the danger. We cordially agree with Carmichael that chloroform is the best anesthetic for children, as ether is apt to cause a profuse flow of bronchial mucus, and this mucus collects and impedes respiration.]

Gay[2] of Boston discusses the present state of anesthesia. He holds that in view of the public opinion of the safety of **ether as compared with chloroform** it is dangerous to the surgeon to give chloroform. If an ill result happens in ether, he may escape blame; if it happens in chloroform, he will be severely censured. Some surgeons prefer chloroform, with good reason, in certain cases. It is quite true, though, that the accumulated testimony of 50 years proves that ether kills slowly, chloroform quickly; that ether kills by the lungs, and chloroform by the heart; that ether gives warning of danger, and chloroform often gives none; that ether is safer in healthy and strong people than in the weak and prostrated, but that chloroform is

[1] Archives of Pediatrics, Sept., 1895.

[2] Therap. Gaz., Nov. 15, 1895.

nearly as dangerous in the vigorous as in the debilitated. Ether requires no special skill in administration, chloroform does. Treatment usually promptly overcomes unfavorable symptoms from ether, and often does no good whatever in accidents from chloroform. Ether is the safest general anesthetic known, and chloroform is not. Hence the burden of proof in the justification of chloroform rests with the operator. Deaths, however, are liable to occur with ether which could not have been anticipated. Chloroform has some notable advantages over ether. Its action is more rapid, it is less unpleasant to take, it is less irritating to the respiratory organs, and is less apt to produce nausea and vomiting. Gay maintains that it is justifiable to employ chloroform in operations upon the respiratory organs. Death from suffocation might occur in these cases when ether is given which would have been escaped if chloroform had been administered. In some cases ether produces great trouble with the respiratory organs and severe after-effects, notably shock. [Genet from a study of thousands of cases considers it proved that ether is safer than chloroform. We agree with Gay that children can be safely anesthetized with chloroform, and also agree with him in the statement that ether may produce serious after-effects.]

Gerster[1] gives the results in 100 cases where he employed **Rosenberg's method** of cocainizing the nasal mucous membrane before and during anesthesia. He gave chloroform in 52 cases, ether in 24, and the A.C.E. mixture in 13. In the other 11 cases more than one of these anesthetics were employed. He found that the feeling of suffocation is often absent at the beginning of anesthesia, this being due to the absence of the patient's perception of the odor of the anesthetic. He found there was very little reflex irritation, which was shown by the infrequency of struggling and coughing, and he noticed that nausea was extremely rare. In a number of these cases there were rapid pulse and great pallor, which he believed were due directly to the cocain. Vomiting followed in only 25% of the cases. [The experiments of Rosenberg and Guerin upon the value of cocainizing the nares before and during chloroform-anesthesia will be found in the *Year-Book* for 1896, p. 328.]

Weir[2] maintains that **ether-anesthesia does not irritate the kidneys,** as is generally believed. He thinks that it has no marked effect upon healthy kidneys, that it is not dangerous in persons with slight kidney disease, and that any circulatory disturbance which may arise in the kidneys very quickly disappears. He reports a large number of cases and considers the views of other observers. [The *Year-Book* for 1896 sets forth the divergent views upon this point, and comments on more of the contradictory statements which have been made. Wunderlich from a statistical study concluded that albuminuria was more apt to be induced by chloroform than by ether. Beck from a statistical study concluded that albuminuria was most apt to be caused by ether. We are thus confronted with carefully compiled reports which are diametrically opposed and absolutely contradictory. The humble surgeon who

[1] Ann. of Surg., Jan., 1896.

[2] N. Y. Med. Jour., Nov. 16, 1895.

venerates statistics too much to use them is lost in uncertainty. We are told that figures cannot lie, and yet only one of these statements can be true. Which is the truth we cannot as yet decide, as we know of no birthmark to prove identity.]

Eisendrath[1] has studied the **influence of ether and chloroform upon the kidneys.** He sums up his results as follows: That though some observers have found that ether had almost no influence on the kidneys, the majority believe that it has a distinct influence on the healthy organs; that this influence is very slight, and is exhibited by traces of albumin and of the varieties of renal elements, and the effects rarely last more than 24 hours; that upon the diseased kidney ether has a highly injurious influence, causing a positive increase in the amount of albumin and the former renal elements. Chloroform acts like ether upon the normal kidney, although its effects last longer and vary in degree according to the length of anesthesia; very protracted chloroform-anesthesia can produce such change in the renal tissues as to even cause death. Upon the diseased kidney, except the amyloid form, its influence is far less injurious than ether.

Eisendrath maintains positively that ether should be used in protracted anesthesia, provided there is no contraindication in the condition of the lungs and heart. In cases of nephritis without secondary degeneration of the heart-muscle, which would be a contraindication to the use of chloroform, the latter agent is preferred to ether. [Patein made 70 observations upon the urine of patients taking chloroform. In 12% of cases albuminuria existed before anesthesia; in 15% of cases albuminuria existed before operation, but during anesthesia; in 73% of cases after operation. He states that the albuminuria usually disappears in a couple of days, and is not developed in proportion to the length of anesthesia. The condition is the passage of serum-albumin at the glomerulus; uric acid and chlorids are somewhat increased. The kidneys are not seriously damaged. H. Fenter has asserted that ether does not affect the healthy kidney, and is not dangerous when the kidneys are but little diseased. In 500 ether cases Butler found albumin only once. In 600 ether cases Kute found albumin 6 times. Selbach says even very prolonged etherization never produces nephritis. Wood thinks that etherization may induce nephritis if the kidneys are diseased. Wunderlich says ether-nephritis does not occur, but chloroform-nephritis does. Becker says acetonuria is apt to appear after etherization. Thus do the masters differ. What are we to believe?]

Cole[2] has made a report upon the use of **oxygen-gas with ether** for anesthesia. He states that the idea of employing oxygen was suggested by a chemist named Carson, who had never seen an ether-narcosis. The necessary paraphernalia are these: Pure oxygen and good ether; a tube 2 ft. in length leading from the cone to the bottle of ether, and another from the same leading to a tank of oxygen; a cone that receives and retains the vapor and that fits snugly over the patient's face, and so arranged that at a little distance

[1] Chicago Med. Recorder, Feb., 1896.

[2] Med. Rec., Oct. 12, 1895.

from the patient's mouth a piece of gauze can be retained moistened with ether, so that ether can be added if necessary without removing the cone. This latter appliance is really not necessary, because it is not difficult to produce anesthesia with only the oxygen-ether. Cole reports a number of cases. The amount of gas used has averaged a gallon a minute. The amount of ether used has averaged for an adult 6 oz., and for a child 3 oz. an hour. The longest time required to obtain complete anesthesia has been 15 minutes, the shortest time less than 3 minutes. The time of recovery has been from 15 to 50 minutes. Salivation necessitating the cleansing of the pharynx occurred in only 1 case. There has been no troublesome vomiting in any case, and in the majority there was no nausea during administration or during recovery. Whenever the flow of oxygen was increased the rapidity of the heart's action was increased; there was easy respiration, no struggling, and no sense of suffocation; in some cases in which temperature was taken no change was noted. [Our experience with oxygen-ether is that it delays anesthesia and never expedites it. It delays it in the same manner air would if mixed in large quantity with the vapor. Further, some cases are not completely anesthetized. We believe in oxygen to arouse patients from ether and prevent unpleasant after-effects, but are not as yet fully persuaded of its value when mixed with ether as an aid and safeguard to anesthesia. Bryant has noted that it requires a long time to anesthetize with the mixed gas, and the anesthesia may not be complete. Curtis does not find the method an improvement. McCosh thinks the oxygen-ether anesthesia is not obtained for a long time and is apt to be incomplete.]

Morrison [1] holds that **oxygen** is extremely valuable in **overcoming the after-effects of ether** in surgical operations. He thinks that it overcomes the nausea and the general depression at once, and cites some cases to prove this contention. He admits that some cases are more benefited from its use than others. In the most favorable cases the results are astonishing. The nausea is relieved or prevented, consciousness is quickly recovered, the breath is entirely deprived of the odor of ether in a short time, and the feeling of malaise is absent. Some few cases are not benefited or are positively harmed by its use. The best method of administering the oxygen for etherization is by the use of a soft-rubber catheter introduced into the nares until the eye of the catheter is opposite the opening in the trachea. [In the Jefferson Hospital this method has been largely employed, and has given great satisfaction. Landau of Berlin has used this plan extensively. He maintains that it prevents headache and nausea, that it abolishes in a moment or two the dusky hue of the face, that it strengthens the pulse, and causes a rapid return to consciousness. Parvin has strongly commended the method.]

Souchon [2] in an article upon uninterrupted anesthesia in operations upon the face and mouth describes his **perfected apparatus** by means of which we can administer chloroform alone, ether alone, or chloroform with ether. A tube is introduced through the nares, and there is not the slightest risk of

[1] Boston M. and S. Jour., Apr. 16, 1896.

[2] Med. News, Nov. 23, 1895.

injecting liquid anesthetic into the pharynx regardless of the force applied to the bulb. [We have used Souchon's apparatus, and think it a valuable aid to operations about the face and mouth. We commented upon it last year.]

The **statistics on anesthesia** are continued by Prof. Gurlt of Berlin.[1] He gives a total of 52,677 narcoses: 31,083 were with chloroform, 15,712 with ether, 2148 with chloroform and ether, 1554 with Billroth's chloroform-ether-alcohol mixture, 1426 with bromethyl, 32 with pental; there were 23 deaths unquestionably due to chloroform, and 8 deaths possibly due to it. Among the cases to which ether was given 5 deaths were due to it, and 1 possibly due to it. There was not a death with the Billroth mixture. Statistics for 5 years show 1 death to every 2909 chloroform-administrations, 1 death to every 6004 ether-administrations, 1 death to every 10,162 with ether and chloroform, and 1 death to 5745 with Billroth's mixture. Gurlt says it is true that ether statistics are better than the chloroform, but ether-anesthesia is often followed by pneumonia. In 30 cases of postanesthetic pneumonia there were 15 deaths; 13 of these cases of pneumonia occurred after abdominal operations. This seems to be due to the fact that abdominal pain causes the patient to suppress the cough. Hence ether-anesthesia is improper for operations upon the abdomen. [The Medical Press and Circular has stated [2] that during the past year there were in the United Kingdom 61 deaths from anesthetics. Schleich says the more the boiling-point of an agent differs from the body-temperature the more dangerous it is as an anesthetic. He has made a mixture of chloroform and petroleum-ether, which mixture boils at the body-temperature, and with this mixture as an anesthetic he has had excellent success, and has met with no dangerous symptoms and no unpleasant results.]

Keefe [3] holds that a patient with a **weak heart** should take **digitalis** for 24 hours before an anesthetic is administered, and should be given a hypodermic injection of a considerable dose just before beginning the administration of the agent. The dose of anesthetic should always be measured. Half an ounce of chloroform is the proper dose to produce anesthesia in a healthy adult, and this should be poured on at once, no more being used except as required to keep up anesthesia; $1\frac{1}{2}$ oz. of ether is enough to render a woman unconscious, and 2 is enough to secure anesthesia in a man. The face, pulse, and respiration should be carefully watched during the administration of chloroform. The respiration and pulse should be carefully watched during the administration of ether. The anesthetizer must not only see the chest move, but must hear the air enter into the lungs. Keefe believes in the combination of chloroform and ether, holding that the stage of excitement is far shorter in duration than when ether is given alone.

Lauder Brunton [4] has made an elaborate study of **chloroform anesthesia.** He says that experiments upon animals have amply demonstrated that when chloroform is inhaled, and not forced into the lungs, death ensues by

[1] Ann. of Surg., Feb., 1896.
[2] Jan. 22, 1896.
[3] Boston M. and S. Jour., Nov. 28, 1895.
[4] Lancet, Nos. 3750 and 3751.

paralysis of the respiratory center, and clinical observation has shown that failure of respiration not unusually occurs during the administration of the drug for surgical purposes. Death may arise from paralysis of respiration, but may also be due to syncope or to cessation of respiration and circulation together, which condition he calls neuroparalysis. Anesthetics never produce neuroparalysis, but rather tend to lessen shock, unless they are administered in such a way as to cause great irritation of the respiratory passages. Choking is apt to arise during imperfect anesthesia, either at the beginning or the end of the administration, and in these cases death by neuroparalysis may arise or death by asphyxia. A patient can usually be reacted from asphyxia by artificial respiration, but neuroparalysis is highly dangerous, and the surgeon should seek to avoid it by removing every cause which might interfere with respiration. The nerve centers are depressed during full anesthesia, and there is more risk of asphyxia than neuroparalysis, but when the reflexes are present, as at the beginning or the end of anesthesia, the respiration must be looked to with the most scrupulous care. The respiration is of far more importance than the pulse. [In spite of the great authority of the distinguished scientist quoted above, we feel sure that deaths have occurred under chloroform from heart paralysis, without signs of respiratory failure. We feel sure of it because most capable surgeons, men well fitted to make accurate clinical reports, have stated so with emphasis. Among surgeons the opinion is general that chloroform kills by way of the heart, and this opinion is drawn from clinical observation. White has, we believe, demonstrated, and so have Percy, Snow, and Richardson, that a large amount of chloroform given rapidly may paralyze the heart, while respiratory failure may happen when the chloroform is given gradually. In rapid administration the circulation is in danger, in slow administration the respiration is in danger. Leonard Hill has recently made a very important contribution to science in a book called "The Physiology and Pathology of the Cerebral Circulation." He maintains that an anesthetic produces a fall of blood-pressure, due partly to vasomotor paralysis and partly to cardiac failure. He shows the interesting point that when the blood-pressure is rapidly sinking, recovery can be brought about by elevating the feet and making pressure upon the abdomen. Ether produces a slow fall of blood-pressure, and chloroform a rapid fall.]

Fingland[1] says that from 8 A. M. to 10 A. M. is **the best hour for the administration** of an anesthetic, as most patients are more cheerful in the morning.

Rein[2] of Moscow maintains that the **transfusion with salt-solution** is of very high value in cardiac paralysis from chloroform-inhalation. This was proved upon animals and has been confirmed upon man. [The difficulty is that cardiac paralysis is apt to take place with such rapidity that transfusion would be impossible unless the tube were inserted into the vein before the operation. There can be no question that transfusion of salt-solution is a powerful stimulant and the very best treatment for severe shock.]

[2] Centralbl. f. Chir., No. 17, 1895.

Edward Martin [1] in an article upon the **Laborde method of artificial respiration** has reported 7 striking cases to show its value. He says that laboratory-experiments and clinical observation show beyond controversy the value of Laborde's method, and when but one method of artificial respiration can be adopted it is preeminently the best. Any form of artificial respiration, unless the tongue is drawn well forward at the same time, is about as successful in accomplishing results as would an effort to fill a bottle without removing the cork. The Laborde method of rhythmical traction upon the tongue is supplemented by the Sylvester method of artificial respiration during expiratory movements. The Laborde method should be taught as the first and most efficient means of resuscitating the apparently dead.

Fell [2] again advocates the method of **forced artificial respiration** in saving life in chloroform, ether, and nitrous-oxid narcosis. He records a remarkable case in which it was used 4 days and 3 nights upon a physician, with the result that his life was saved. [Fell makes forced respiration by means of a bellows, the air being driven into the lungs through the mouth or through a tracheal tube. Parmenter has spoken highly of the method. In case of collapse during anesthesia tracheotomy is approved of by Poncet, Vanverts, and others. Poncet says it permits of free entry of air by artificial respiration, it allows air to be forced in, and does not interfere with tongue-traction. Eight successful cases have been reported. (See Delaup, New Orleans Med. and Surg. Jour., Apr., 1896.) Tracheotomy acts mechanically when narcosis is due to obstruction, but it is valuable in cases where no obstruction exists, and even when the patient is apparently dead. In these latter cases the action cannot be mechanical. Delaup says it is reflex, and holds that the operation excites the cardiac and respiratory centers, the factors in the reflex stimulation being the incision, the presence of the tube, and the entry of cold air. This procedure is to be resorted to only when other measures fail.]

Prescott [3] maintains that etherization does not cause acute **lobar pneumonia.** He did not find any reference to it in literature, though there is a general concurrence that ether is a cause. He finds the record of bronchopneumonia and inhalation-pneumonia following anesthesia, but does not find any of true lobar pneumonia. The records showed 40,000 cases of etherization, with 3 cases of acute lobar pneumonia. When we reflect on the enormous number of people etherized and the very small number of pneumonias, we are justified in concluding that ether is very rarely the cause of the pneumonia, and that the 3 cases above mentioned may have been merely coincidences. [Occasionally a pneumonia arises after operation, and it is difficult to determine whether ether or chilling of the body was the cause.]

Charles Phelps [4] places on record an interesting and important case in which **vomiting** occurred **during anesthesia** from ether, the result being that the patient was asphyxiated. [Vomiting is apt to occur when the patient

[1] Therap. Gaz., Dec. 16, 1895.
[2] N. Y. Med. Rec., May 30, 1896.
[3] Boston M. and S. Jour., 1895, cxxxii.
[4] N. Y. Med. Jour., Mar. 21, 1896.

is passing into the anesthetic state if the stomach contains food. During anesthesia vomiting may be due to letting the patient come partly out of ether, and the remedy for this is more of the anesthetic. Vomiting may be due to forcing a large quantity of ether upon the patient, and the remedy for this is a breath or two of air and then gradual anesthetization. Occasionally, in spite of scrupulous care, such an accident as noted above may happen. Out-patients who come to have small operations done frequently violate explicit directions and eat largely before operation, and deny positively that they have eaten. In dealing with accident-cases we may find the stomach full. When a patient vomits, the body and head should be turned upon the side, so that the vomited matter will run out of the mouth, and not into the windpipe, and after vomiting the mouth and pharynx should be swabbed out. A patient should be watched after the use of an anesthetic until consciousness returns, lest vomiting or some other accident occur.]

Buxton, the distinguished anesthetizer of University College Hospital in London,[1] presents a very able paper upon **the nature of anesthesia.** He discusses the paths of anesthesia; the peripheral sense-organs; the production of anesthesia; the action of anesthetics; the definition of anesthesia; true and false anesthesia; theories of anesthesia; and effects produced by anesthetics. The article should be read in full by all surgeons. It is original, forceful, and scientific, and cannot be justly represented by limited quotation.

In conclusion, Buxton says: "What, then, are the practical lessons our present knowledge teaches us? In general we must conclude that the action of the anesthetic should be restricted within those clearly defined limits which involve only the higher ganglionic centers—that under no circumstances should incomplete anesthesia be deemed sufficient for even the most trivial operation.

"Of methods our present knowledge allows us to say much, but it is impossible for me to do more than indicate in the briefest way what rules should guide us. All methods involving asphyxial symptoms are open to grave censure. In the case of all anesthetics it is possible to produce unconsciousness and yet to avoid cyanosis. Nitrous-oxid gas, once thought to be an asphyxiant, is now known to be a true anesthetic, and to be capable of being given with oxygen or air, and to produce peaceful anesthesia without any asphyxial phenomena. Of ether the same is true. Of chloroform it must be said that any association between it and asphyxia must lead in the healthy subject to grave peril and in the diseased to fatal results.

"A word further. Close study of the behavior of anesthetics makes me certain that all methods which employ a large quantity of anesthetic substances are faulty. The pneumonia, the renal catarrh, the cardiac asthenia following anesthesia are due, in most cases, not so much to the anesthetic as to the unwary way in which it is employed. When anesthesia is better understood, and those who employ anesthetics recognize more the responsibility they incur, when the examining boards demand of their candidates at least a nodding acquaintance with anesthetics and their uses, then will there

[1] Lancet, Feb. 1, 1896.

be fewer fatalities and more common-sense practice of this branch of the healing art."

Bayer[1] presents a note upon the danger of **anesthetizing diabetics.** He says that a patient with even slight diabetes is apt to become comatose and die under the use of a small amount of anesthetic. He has reported 3 cases of his own and has collected 9 from literature. The coma developed in his cases after the chloroform-narcosis had entirely passed away—that is, from 24 to 48 hours after the operation. It is impossible to predict whether coma will arise or not in diabetics. [Becker of Bonn has published cases in which rapid diabetic coma followed anesthesia, the condition being due to acetonuria. He made an investigation to find out if anesthesia can produce acetonuria in healthy people, and he found that it does so in most of them. The degree of acetonuria bears no relation to the severity of the operation, or the duration of the narcosis, or the form of disease. It usually disappears by the fourth day, but may last for 8 or 9 days. In 1 case Becker found acetone 20 minutes after the beginning of anesthesia. In diabetics the existing amount of acetone is greatly increased. Acetonuria is more certainly induced in children than in adults. This condition bodes no danger to a healthy person, but does to diabetics. (For a consideration of this subject see Tr. Am. Med. Assoc., Jan. 4, 1896, and Therap. Gaz., May 15, 1896.)]

TUMORS AND CYSTS.

The records of an **implantation dermoid tumor of the cranial cavity** are presented by Hartley.[2] The woman was 46 years of age, and received a blow on the head 10 years ago which produced what is believed to have been a slight compound fracture of the skull. For 2 years there was depression, but after this period a prominence became notable upon the forehead to the left of the median line. The tumor was $1\frac{1}{2}$ in. in diameter and $\frac{1}{2}$ in. in height. It was not adherent to the overlying skin. Deep pressure disclosed the fact that there was an irregular bony opening. The tumor did not pulsate. Hartley performed an operation, dissected up the flap of skin and subcutaneous tissue, and found beneath this flap a layer of tissue continuous with the periosteum at the margin of the tumor. The only point at which it was adherent to the skin was opposite to the center of the flap. When this layer was divided an irregularly rounded opening in the frontal bone was disclosed, and behind this opening lay an encapsuled gelatinous mass, the capsule of which was continuous with the layer above as well as with the dura mater. This tumor was removed, the soft gelatinous material which it contained being first spooned out. The cavity was packed with iodoform-gauze and the patient made a complete recovery. The microscopic examination disclosed the fact that the tumor was a dermoid. It was obviously not an endothelioma, as the cyst-wall was distinctly epidermal and did not contain any endothelial cells. It was evidently due to an accidental transplantation of a portion of the surface epithelium or of some of the hair bulbs

[1] Boston M. and S. Jour., July 11, 1895.

[2] Ann. of Surg., May, 1896.

into the underlying connective tissue. Hartley says that this form of cyst is most frequently met on the fingers of shoemakers, carpenters, and tailors, and was first described by Muron in 1868, though he did not realize that injury was the cause. Hartley then reviews the very interesting literature of this subject. He tells us that a fragment of skin may often be carried in at the time of the injury; that, as a rule, the injury kills this piece of skin or disposes of it in the process of healing, but once in a great many thousand times this fragment retains vitality, and after a dormant period of from 4 months to 2 years develops a cyst. [The *Year-Book* for 1896 presents an abstract of Le Fort's valuable article upon traumatic dermoid cysts, p. 182.]

The treatment of malignant tumors by the toxins of erysipelas still occupies considerable attention. Roberts [1] reports 3 cases within the past 6 months, not one of which was benefited. Campanini [2] reports 2 cases in which the treatment was a failure, histologic examination of the tumor showing the absence of any progressive changes. Campanini holds that the treatment is useless, and that serious symptoms often arise during its application. Friedrich [3] treated 13 cases of epithelial carcinoma and 4 cases of sarcoma, the latter comprising 1 endothelioma, 1 osteo-fibro-chondro-sarcoma, and 2 lymphosarcomata. He says that in the case of the cancers some subjective improvement occurred, but in no sense a cure. In the sarcoma the treatment did not obviate the inevitable results. In 1 case, however, there was an improvement which lasted a long time. Injection into the tumor tissue caused redness, swelling, and edema, and in some cases necrosis of the tissues, which necrosis in many cases extended to the tumor base. Metastases were absolutely unaffected by the treatment. After subcutaneous injection a large area of infiltration appeared which did not disappear for 48 hours. Czerny [4] describes his experience with this treatment. He used the mixed toxins of erysipelas and bacillus prodigiosus. He has treated 8 cases—4 of sarcoma and 4 of carcinoma. One case of small round-celled sarcoma was greatly benefited, but at the time of the report was not cured. Czerny says, however, that this 1 case is not absolute proof of the value of the agent, since the patient at the time of treatment was pregnant, and it is well known that tumors such as sarcoma, epulis, and osteophytes sometimes disappear spontaneously, particularly after confinement. The other cases of sarcoma showed but a trivial change; 3 of the cases of cancer were not improved, 1 case was somewhat improved. Czerny concludes that the materials collected are too scanty to admit of the formulation of positive rules for the treatment of malignant tumors, but nevertheless it is desirable to thoroughly test these toxins. He thinks that the injections exercise a specific influence on sarcoma, and under specially favorable circumstances may cure it, causing the tumor to become edematous, to shrivel up and be absorbed, or else to soften and slough. The method, however, cannot take the place of operation, and it is employed only

[1] Med. News, 1895, No. 2, p. 606.
[2] Il Policlinico, July 1, 1895.
[3] Verhandl. der Deutsch. Gessel. f. Chir., XXIV Kongress, 1895.
[4] Münch. med. Woch., Sept. 3, 1895.

in case of inoperable tumors or recurrent tumors or after operation for sarcoma to guard against recurrence. In cancer the injections may delay the progress of the case, but will not cure it. Swain [1] writes an article upon the treatment of malignant tumors by these toxins, and presents a record of unsuccessful cases. McBurney has presented 3 unsuccessful cases. Senn [2] has reviewed this treatment elaborately from the time it originated to the present, and has no faith in it whatever.

[Coley himself and some other observers still maintain the view that the method is of great value. We see no occasion to alter the view we expressed in the *Year-Book* for 1896—that is, that our experience has not been such as to produce faith in the method. Selva has strongly set forth the discrepancy between the clinical reports of Coley and pathological evidences of Councilman. We firmly believe that many reported cures were really instances of mistaken diagnosis. When arguing in favor of the specific curative effect of the toxins one should remember that cures of sarcomata have been reported by high authorities as having been obtained by the injection of alcohol, of anilin, of zinc chlorid, and of other materials. Roswell Park in his recent work upon Surgery says that the toxins are, as a rule, pyogenic and depressing, and that the amount requisite to affect the tumor cells may be more than the general organism can stand with safety. He further says there is reason to think that many different substances when introduced into the system may favorably affect malignant growth *for a short* time, but these results are usually temporary. On March 27, 1895, the New York Surgical Society appointed a committee to investigate the use of erysipelas-toxin and to report upon its value. This committee consisted of Drs. L. A. Stimson, A. G. Gerster, and B. F. Curtis, and it reported on March 25, 1896 (see Annals of Surgery, July, 1896). The report declares that the committee has not found in a single case any amelioration which held out a prospect of cure. In some cases the toxins appeared to hasten the growth of the tumor, and in most cases hastened the cachexia. The report says: "1. The danger of the treatment is very great. 2. The alleged successes are few and doubtful in character, and the most that can be fairly claimed for the treatment by toxins is that it may offer a slight chance of amelioration. 3. Valuable time is often lost in operable cases by pursuing the treatment. 4. The method should never be resorted to except in absolutely inoperable cases."]

The subject of **serum-therapy** in malignant growths was presented in the *Year-Book* of last year, when we discussed the article of Emmerich and Scholl. Domergue [3] reviews the recent observations of Emmerich and Scholl, and maintains that we are justified in applying serum-therapy only to cases of disease due to microorganisms. Cancer is not such a disease, and the facts set forth to prove that serum injections, injections of erysipelas-toxins, or of the juice of a sarcoma are curative prove nothing more than the facts which have been set forth to maintain the curative influence of phosphorus, picric acid,

[1] Brit. Med. Jour., Dec. 7, 1895. [2] Jour. Am. Med. Assoc., July 27, 1895.
[3] Presse méd., June 1, 1895.

anilin, and other agents. These latter materials when injected cause aseptic necrosis. The area of necrosis attracts the white blood-corpuscles, and a true and partial absorption of the tumor takes place. The toxins of erysipelas may occasionally lead to the same result, but the whole disease is never cured. The Centralblatt für Chirurgie, Jan. 11, 1896, comments on some 50 reported cases in which the French observers have used serum-therapy. The experimenters maintain that serum treatment causes great abatement in pain, diminution in hemorrhage, improvement in the ulceration, and favors a tendency to the formation of granulations and scabs; they further assert that under its influence the swelling diminishes, that adjacent infiltrations shrink, that infected glands decrease in size, and that the entire cancer decreases in size—that even in the most severe cases the development of the cancer is positively hindered and the general health is much improved. Bruns[1] treated 5 cancers and 1 malignant lymphoma by this method. In not a single case did the injections prove of the slightest benefit in diminishing the growth of the tumor. Bruns examined the serum and found that it was completely sterile. [The serum-treatment is based upon the same theory as is the antitoxin-treatment of infectious diseases. An animal, usually a horse, is injected repeatedly with fluid obtained from a cancer or with a fluid extract made from cancer. The earliest injections produce some disturbance of the system; the later injections do not excite any reaction. When injections cease to excite any reaction blood is drawn from the animal; the serum is separated and is injected into the patient. Emmerich and Scholl obtain the serum from a "prepared" sheep, and filter the serum before using. Other observers have employed goats, dogs, and asses. The value of this method is entirely problematical.]

The Etiology, Diagnosis, and Treatment of Malignant Disease is the title of an elaborate and able paper by Dennis.[2] It was the presidential address of 1895 before the American Surgical Association. He reviews the whole subject, and every surgeon should read it. Dr. Dennis comments on the unreliability of the statistics in regard to the permanent cure of malignant disease, and he says that the unreliability lies in the fact that surgeons report cures of malignant disease in cases in which the tumors are innocent. He lays down a rule to which there should be no exception: that is, before a tumor is classed as malignant it must be subjected to a microscopic examination by a skilful pathologist, and if this condition has not been complied with, the case must not be admitted into any list of cures. The author does not accept the germ theory of malignant disease. He tells us that the weight of opinion is opposed to it, and that clinical evidence points strongly in favor of the view that changes of an inflammatory nature are responsible for the development of malignant tumors. Mechanic injury is associated with the causation, sarcoma and peripheral irritation with carcinoma. In discussing **eczema of the nipple** Dennis says it is different from the simple eczema observed in other parts, since the usual conditions are absent, such as irritable and dry skin, overwork, anxiety, faulty innervation, vasomotor

[1] Jour. de Méd. et de Chir., Nov. 25, 1895.

[2] Ann. of Surg., Oct., 1895.

disturbances, the uric-acid diathesis, impaired kidney secretion, dyspepsia, etc. It is found where there is no friction or moisture. The disease does not disappear by the use of those agents which cure simple eczema. This eczema is local at first, but its continuous irritation will cause proliferation of the epithelium in the milk ducts. It is at first a chronic affection located in the skin about the areola of the nipple, never extending deep into the tissues. But when this form of eczema occurs in women who have passed the menopause it is very likely to give rise to epithelioma. The eczema is not secondary to breast-epithelioma, since it antedates any evidence of disease in the ducts. The common cause of irritation in the mouth is nicotin. Cases of epithelioma starting in the mouth are often due to this cause. An illustration of the law that persistent irritation of the mouth may cause epithelioma is found in the liability of those who nail laths to get cancer of the tongue, because of the custom of these mechanics to introduce the nails into the mouth and push them out by the tip of the tongue as they are needed. Illustrations of the law that continued irritation is likely to give origin to cancer are seen in the irritation produced by a clay pipe on the lip, and in the irritation produced by the continued pressure of a pair of eyeglasses, and the cases reported by Gerster of rectal epithelioma in patients who were in the habit of carelessly using the nozzle of an injection-syringe. A discharging sinus is a source of irritation to a patient, because the continuous irritation of the discharge of acrid pus may lead to the development of epithelioma. The theory of Cohnheim, that tumors arise from the proliferation of embryonic cells which were displaced during fetal life, and which rapidly multiply in consequence of some exciting cause, cannot be rejected, and any attempt to explain tumor-formation except from vestiges seems futile.

He then considers different special forms of malignant disease, sarcoma in different regions and carcinoma in different regions. He tells us that in England alone there are 7000 deaths annually from carcinoma, and that this disease causes more deaths in the United States in one year than the sum total of deaths due to erysipelas, tetanus, hydrophobia, lightning, typhlitis, gunshot wounds, joint-disease, together with other well-known affections. In the United States cancer in one year causes nearly half as many deaths as are caused by accidents and injuries of all kinds and descriptions—that is, about 14,000 deaths a year.

Dennis analyzed Halsted's figures in regard to the cure of **cancer of the breast,** which have been considered the best published up to that time. Halsted claims that he had 6% of recurrences locally in 50 cases which he reported in 1894; but of these 50 cases the results of 5 he records as unknown, and 25 of them he reports not having reached the 3 years' limit of time. Therefore only 20 cases, instead of 50, can be used in estimating the local or regionary recurrences. Of these 20 cases, 18 died before the 3-year limit was reached, leaving only 2 in which recovery can justly be said to have taken place. Hence Halsted's figures ought to show 10% of permanent cures and 15% of local recurrences, since in the 20 cases there were 3 local recurrences.

Dennis has had 116 cases of breast-tumor, of which 19 were not operated upon, leaving 97 cases in which the breast was removed. In these 97 cases there was 1 death, a mortality of a little over 1%, and this death was due to the presence of hemophilia, and would have occurred no matter what operation had been undertaken. From the mortality of Billroth, 23%, to the present possibility, shows the enormous reduction which has taken place. Of the 97 cases, 74 were carcinoma, and the subsequent histories of 41 are known; 3 of these have not yet reached the 3-year limit of time, and there remain 38 cases with full subsequent histories. In these 38 cases there were 17 cases of recovery, or 45% of permanent cures, and among these 38 cases there were but 2 local recurrences—a little over 5%. Since the publication of the writer's last statistics in 1891 he has had 15 cases of pure carcinoma of the breast without a death. In 13 of these cases full subsequent histories are known: 2 of these died from recurrence and 1 from hemophilia, and the remaining 10 have passed the 3-year limit of time. This gives 77% of permanent cures in the last 15 consecutive cases. In the cases of sarcoma of the breast the subsequent histories are all known: 4 of these cases were cured, 66⅔%, and 2 died from a return of the disease. [Dennis thinks the harpoon a valuable aid to diagnosis. We do not so consider it. Small fragments so obtained do not show the structure of the growth, and more often lead to error than to truth. We have seen evidence of this several times.]

The Lettsomian Lectures for 1896 were delivered by Cheyne,[1] who chose as his subject "**The Objects and Limits of Operations for Cancer.**" He has presented most ably and impressively his views. This article contains within itself not only the condensation of most of the recent literature upon this subject, but the present views of a surgeon of wide experience, of high scientific attainments, and of great practical skill. These lectures constitute one of the most notable articles of the year. Cheyne's primary proposition is that cancer is, in the first place, a local disease—that early removal and thorough removal means a cure, and that a cure may be obtained in some cases even after recurrence. When a visible portion of disease is left recurrence takes place almost at once, and when invisible portions are left it takes place in most cases within one year. Recurrences are rare after a year, and Volkmann has proved that after 3 years they very rarely happen. Reappearance after 3 years is usually fresh development rather than recurrence, although later recurrences can take place in glands where the cells may have remained dormant from the time of the previous operation. He cites a case where a breast was removed for a cancer 15 years before. A few small glands had been left untouched in the axilla, and only began to enlarge after 15 years. The younger Gross has shown that of all recurrences after breast-operations only 2.3% take place after 3 years. Hence Volkmann's 3-year limit. Freedom from recurrence for 3 years is estimated as a cure. The prospect of cure of cancer is excellent when the growth is superficial and there is room for cutting wide of it. In epithelioma of an extremity the cells are not so small

[1] Lancet, Feb. 15, Feb. 22, and Mar. 14, 1896.

as in cancer of the breast, and hence remain local longer, and the surgeon by amputation can go wide of the disease. Volkmann showed that 51% of such cases could be cured. Cancer on the face gives a rather favorable prognosis, and free removal often brings about a cure. The least favorable of face-cases is lip-cancer, because the muscles are attacked early. But even in lip-cancer Bruns has had 38.2% of complete recoveries and Maiweg at Bonn has had 44%. The combined results of many German operators show that 28.1% are cured.

Jones and Platt[1] consider the **results of operations for cancer of the breast** which were performed at the Manchester Royal Infirmary during a period of 10 years. They form the following conclusions: Cancer of the breast is amenable to treatment by operation, and 12% of cures can be confidently looked for. Nonsuccess in operation is generally due to the extensive character of the disease when the patient first seeks relief. The earlier the operation the greater the proportion of cures. Moderate axillary enlargement does not forbid operation and is not a bar to a successful issue, provided that the axillary space is thoroughly clear. It is impossible to demonstrate slight enlargement of the axillary glands by examining through unbroken skin. No operation for cancer of the breast is complete unless the axilla is examined through the wound. A large number of local recurrences show the absolute necessity of freely removing the disease, taking away all doubtful skin, and not leaving any outlying portions of breast tissue. Operations should not be performed when the entire growth is irremovable or when the supraclavicular glands are enlarged. The only conditions which might render an operation proper under such circumstances is the presence of a foul ulcer, the removal of which will greatly modify the inconvenience of the condition. [Some surgeons consider it justifiable to operate when the supraclavicular glands are enlarged, and others maintain that these glands should be removed in breast-cancer even when they are not manifestly enlarged.]

Lane[2] in discussing the **radical operation for malignant disease of the breast** says that in some cases the ordinary operation may be sufficient, but when there is an extensive involvement the large raw surface which the operation leaves as a legacy is a powerful antagonist to recovery. In such cases he amputates the arm at the shoulder in order to obtain enough skin to cover the raw surface. As in such cases the loss of the arm would in any case result from the dissemination of the disease and death would soon follow, we are justified in doing this because we may obtain full recovery with merely the loss of an arm. He reports a case of perfect cure obtained by this method. [When the axillary involvement is so extensive as to require amputation to effect removal, as a general rule the disease has also passed beyond reach. Cheyne in a previously quoted article opposes this operation. He says amputation of the arm can be necessary only when a mass exists in the axilla which involves the vessels and nerves. Involvement of the artery, vein, or even both vessels, does not necessitate amputation, as he has several

[1] Lancet, Aug. 31, 1895.

[2] Ibid., No. 3763.

times removed portions of the vein, and in 1 case he removed both vein and artery without any subsequent loss of vitality in the limb. He thinks if the disease is so diffuse as to involve the nerves, it has certainly extended beyond reach.]

Sanderson[1] makes a contribution to the **surgical treatment of malignant disease of the breast.** He says it is a commonly acknowledged principle that not only should the whole affected mammæ be excised, but that all its lymphatic connections should likewise be removed. He examines the question as to how far this principle is applied in practice. He says that the efferent lymph-vessels run from the axillary glands through the apex of the axillary into the posterior triangle, and, after forming connections with the glands of this triangle, finally enter the thoracic duct on the left side and the right thoracic duct on the right side. Superficial lymphatics from the skin covering the mammary gland pass up over the clavicle to these same glands in the posterior triangle. It is laid down in primary malignant disease of the breast that the breast should be removed, and that then the axilla should be cleared out whether the glands be visibly affected or not. This rule is laid down because it is well known that because glands are not *visibly* affected is no proof that they are not microscopically affected. In the face of these established facts it is not the usual custom for the surgeon to proceed farther than this. If it is wrong to assume that the axilla is free from disease because it shows no microscopic evidence, it is equally wrong to assume that the posterior triangle has escaped. If it is right to clear out the axilla in every case, it is also right to clear out the posterior triangle. It is absolutely inconceivable why the triangle should be left untouched if the axillary glands are found clearly affected at the time of operation. The operation of clearing out the triangle is not a difficult one. A flap formed by an incision along the sternocleidomastoid muscle meeting an incision along the clavicle is detached as far back as the anterior border of the trapezius. This thoroughly exposes the triangle, so that its contents can be readily removed. Sanderson maintains that by such means an acknowledged principle would be thoroughly carried out, and, if the principle is right, it is incumbent upon the surgeon to apply it thoroughly and not to stop halfway. [The glands in the axilla constitute a net interposed between the breast and the cervical glands, and if a case is operated upon reasonably early, the removal of the axillary glands alone does carry out the principle. Nevertheless, in many cases it is wise to open the posterior cervical triangle. It should be done in all cases of rapidly growing cancer, and should be done in all cases where glands at the apex of the axilla are involved. We say it should be done, and yet we think even this gives but little hope. If the cervical glands are involved, it is almost certain that the thorax is invaded, as the route along the subclavian vein into the thorax is taken by the cancer cells *sooner* than the route into the neck. Arbuthnot Lane advises section of the clavicle as a preliminary to clearing out the triangle, but this step is unnecessary.]

[1] Lancet, Dec. 21, 1895.

The clinical lectures on **the diagnosis of carcinoma of the breast** in its earlier stages by Sheild[1] are a notable contribution to practical surgery. Sheild shows us that cancers of the breast form nearly one-half of hospital cases of breast-disease. When the patient is examined the thorax should be quite undressed and covered loosely with a towel or handkerchief, and both breasts should be carefully examined. He then shows the symptoms of the typical case. The common age of onset is between 40 and 55, though Bryant has seen a case in a woman aged 25, and refers to one by Henry of Breslau in a patient of 21. The oldest patient that Sheild has seen was 78, though Bryant has seen a case at 96. Most patients discover quite accidentally that they have a tumor, and anything like severe pain is exceptional in very early cancer. Pain, if present, is neuralgic, and is not associated with throbbing or special tenderness or heat or redness. Carcinoma of the breast is sometimes insidious in onset, especially in very fat women. This fact explains those cases in which the secondary effect of the disease in causing deposit in other parts becomes more noticeable and sooner prominent than the primary effect. A case of insidious pleurisy may be due to a deep-seated nodule of breast-cancer, and the same may be said of many supposed rheumatic pains about the thorax or bones. Spontaneous fracture of the femur may occur in the same class of sufferers, and also severe pains in the spine terminating in paraplegia. In all such cases examine the breasts, and in a certain proportion of them you will find cancer. Sheild reports a case of scirrhus in the breast of a very fat woman which was merely marked by a dimple in the skin; a case of paraplegia due to vertebral deposits of cancer arising from an atrophic scirrhus of the breast; a case of scirrhus of the breast with secondary growths of the spine; a case of scirrhus of the breast with secondary cancer of the spine and ribs; a case of scirrhus of the breast with hydrothorax; and a case of cancer of the liver with concealed cancer of the breast.

In regard to locality in the breast, there is no preference for one side more than the other. Both breasts are affected simultaneously in about 3% of cases. Most of the growths occur in the nipple, and in the larger proportion of them retraction of the nipple is noted. A favorable site is the upper and outer quadrant, but cancer may originate in any portion of the breast-substance, and if it lies very deep or lies far away from the nipple, retraction of that structure may not occur. Occasionally cancer arises at the thoracic mammary junction, and looks as if it were rather in the skin of the thorax than in the breast. As a matter of fact, however, it usually spreads in an outlying lobule of the breast, and quickly infiltrates the skin, forming a circular ulcer. This form of cancer is especially menacing, because it rapidly attacks the chest walls, not being separated from them by the thick mass of the pectoral muscles. There is generally some amount of truth in popular beliefs, and there is no more strongly rooted idea than the hereditary nature of cancer. Sheild believes that in certain individuals peculiarities of structure or growth may

[1] Brit. Med. Jour., May 30, 1896.

be sufficiently pronounced to become hereditary, but family history is of no great value in aiding one to arrive at a certain conclusion.

Paget found a family history of cancer in 33% of cases, Bryant in 12%. Hardness is one of the most striking characteristics of scirrhous cancer, and it is estimated by placing the fingers flat upon the breast over the tumor. The contour is irregular. A dense and thick-walled cyst, a chronic abscess which is distended and surrounded by inflammatory tissue, or an area of tissue thickened by chronic inflammation may all be exceedingly hard. The cancer is not encapsuled and never moves freely, but the surrounding tissue moves with it. In a very fat breast, where the cancer lies in a semifluid medium, it may have a deceptive sense of mobility. Contraction of the nipple is due to a contracting growth drawing upon the larger milk ducts and fibrous tissue. It may be entirely absent in a cancer which is some distance from the nipple. The strongest single symptom of carcinoma is that there is a hard lump near the nipple, which lump goes on progressively increasing while the nipple goes on progressively retracting. The nipple, however, may be retracted from other reasons. Retraction may be simulated by a congenital imperfection. Retraction may take place because of chronic inflammation, especially when associated with an abscess. A cyst which has emptied itself and shrivelled up again causes retraction. Incisions into the breast for cysts or abscesses may be followed by retraction. In a very rapidly growing cancer there is but little fibrous tissue, and it is fibrous tissue which causes the retraction; hence in a very rapidly growing cancer there is no retraction. Sheild then discusses precancerous conditions, especially eczemas of the nipple. The chronic eczema which is associated with lactation will get well under appropriate remedies, but the condition known as Paget's disease, which is not a real eczema, but a malignant dermatitis, persists in spite of all remedies short of extirpation. Paget's disease arises in elderly women. The area becomes red and raw and looks like an acute balanitis. The raw surface weeps a watery and viscid discharge and is the seat of itching and burning. The tissues about it are thickened. The surface is occasionally covered with white scales, and the integument about it not unusually contains livid red blotches. Many observers claim that they have found coccidia in these cases, but the relation of coccidia to cancer has not yet been determined.

Implication of the skin in early carcinoma is of value in arriving at an early diagnosis. You must distinguish between the dimpling of the skin caused by the contractions of cancer pulling upon the fibrous suspensory bands of the breast, and that peculiar puckering of the skin which is seen when the cancer is beginning to infiltrate. The latter condition resembles the dimpling seen on a coarse pigskin saddle. In a fat breast this dimpling may be the earliest sign of the disease, though you may meet with a similar appearance in an old abscess which has ruptured, in shrivelled cysts, or as the result of incisions in the breast. A rapidly growing cancer may not dimple the skin at all. Hard glands are very common in scirrhus, yet they are often absent in early cases, and their absence does not prove the disease innocent.

The presence of enlarged glands does not prove the disease is malignant, because we may find enlarged glands in the axilla in tuberculous breast-disease, in the initial lesion of syphilis, and in inflammatory mastitis. It is impossible to be sure that the glands of the axilla are enlarged in many cases without opening the axillary fascia. Exploratory incision is occasionally necessary in reaching the diagnosis of scirrhus of the breast. Sheild tells us that the following conditions may be confounded with early cancer: Inflammatory conditions, abscesses, cysts, other tumors, as fibroadenoma, sarcoma, or gummatous infiltrations, phantom tumors, keloid of the breast, and syphilitic skin-affections. He discusses each of these affections in a thoroughly practical way, and reinforces his views by the citation of illustrative cases. The entire article is of extreme value, and should be read thoroughly to be appreciated. [This article contains numerous details of the first importance which are not set forth fully in text-books, and which can only be duly considered in lectures. Such a paper proves, if any proof were needed, that those who advise a system of medical education purely by text-book recitation, without lectures, would create a system which would produce ill-informed practitioners.]

Carr,[1] in a paper on **"The Nature and Treatment of Malignant Tumors,"** advises that in breast-tumors the surgeon should begin his operation in the axilla, so as not to force any cancer-cells from the axilla into deeper tissues while manipulating the breast. The author protests against any operation for the onset of marked cancerous cachexia or the appearance of secondary deposits unless the operation is undertaken as a palliative measure. [The younger Gross, years ago, in a number of cases tried opening the axilla before he removed the breast, and gave it up, because he believed that by such a method his removal of the disease was not as thorough as when he began with the gland itself. The statement that operation should not be done if cancerous cachexia exists is not invariably true. Marked cachexia may exist when there are no secondary growths, and operation may cure cachexia by removing the area from which absorption of toxic products is taking place. We have seen this happen. Operation should not be done when secondary deposits exist, provided we do not consider involvement of anatomically related glands as secondary deposit.]

Gouley[2] discusses the **prognosis of malignant tumors,** and holds that malignant tumors are more frequently met than benign tumors, because of the fact that benign tumors have not been removed in the early period of their growth, but have been permitted to become malignant. He holds that many external benign tumors become malignant, and that some external malignant tumors tend to become benign. The vast majority of carcinomata and sarcomata of the mammary gland are developed from adenomata. The early excision of malignant growths does not invariably increase the chance of cure, but it very generally modifies favorably their progress and prolongs the period of immunity from recurrence, often indefinitely. As soon as the tumor recurs, and as often as it recurs, it ought to be excised. The early

[1] Med. News, Jan. 11, 1896.

[2] N. Y. Med. Jour., Dec. 21, 1895.

excision of external innocent tumors is in reality frequently a prophylactic against malignant disease, and scarcely any tumor is too small to be excised. Gouley of course advocates the removal of adjacent connective tissue and lymph glands when we are removing malignant tumor. Applications of nitrate of silver, arsenic, and other escharotics to tumors are generally worse than useless, frequently cause extension of the local trouble, and in malignant disease frequently lead to dissemination in the organs. The value of constitutional treatment after excision of malignant tumors is great, though there is no such thing as a specific. The internal treatment consists in the use of reconstituents and of such means as will aid in establishing the equilibrium of bodily function.

Lowenthal[1] has collected the reports of 800 **tumors of traumatic origin.** He says that while cancers are more often produced by persistent irritation than by mechanic injury, still cases of the latter sort do occur. Authenticated cases which show traumatic origin may be separated into two classes—those in which the wound never heals, but becomes cancerous, or in which, after healing, the scar becomes cancerous; and those in which cancer forms at the seat of injury or is produced in the wound. The length of time between the alleged injury and the appearance of the tumor has been from a few days to 49 years. The old scar may give origin to sarcoma years after the injury. There cannot be the slightest doubt that injury can give origin to a tumor either innocent or malignant. It may do this by stimulating into growth some depot of embryonal tissue or by causing the normal tissue to take on an embryonal growth. The following table gives the report of his cases:

Kind of tumor.	Number of individuals.	Head.	Face.	Neck.	Breast.	Back.	Abdomen.	Urinary organs.	Genital organs.	Pelvis and lumbar region.	Upper extremity.	Lower extremity.	Multiple tumors.

Tilmanns[2] discusses the **etiology and histogenesis of carcinoma.** He believes in the hypothesis of Thiersch-Waldeyer, that carcinoma takes origin from glandular and superficial epithelium which preexisted—that it

[1] Arch. f. klin. Chir., Bd. xlix. Heft. 1 and 2.

[2] Verhandl. der Deutsch. Gesells. f. Chir., XXIV Kongress, 1895.

disarranges the normal tissue structure at the point of origin, forming grooves unconfined at the periphery, and leads to a general infection or death of the patient through growth in the lymph channels or in some few instances through the blood-vessels. Because a growth is atypical it is not necessarily carcinomatous. Carcinoma grows in an irregular manner or is without a capsule, and infiltrates adjacent tissue, and the cells become detached and cause metastases. Carcinoma can easily develop, because of irritation, from an atypical non-malignant growth. The hypothesis of Cohnheim cannot be unreservedly accepted, although it does explain satisfactorily the formation of some tumors, as, for example, dermoid cysts, rhabdomyomata, tumors springing from displaced cells of the suprarenal capsules, from accessory thyroid glands, etc. The most modern view is that of Ribbert, who maintains that carcinoma does not begin in the penetration of epithelial cells in the connective tissue, but from the growth of the subepithelial connective tissue. This subepithelial growth lifts up the epithelial cells, disturbs their proper relation, and envelops them in connective tissue; and these cells then proceed to grow in the lines of least resistance—that is, in the lymphatic passages and the spaces of the connective tissue. Tilmanns exhibits the view of Ribbert as to the origin of cancer, and maintains that in many cases of carcinomatous degeneration the connective-tissue degeneration remains entirely passive. It is held by Hauser that metastases do not invariably form in carcinoma. Tilmanns does not believe that the cells possess any outward sign by which they can be differentiated from normal tissue cells. The bacterial origin of carcinoma is entirely unproved, and even the presence of sporozoa has not been satisfactorily demonstrated. In some instances the transplantation of carcinoma has taken place. This occurs by autoinfection or by infection from one animal to another of the same species. But transplantation from one species of animal to another species has never been successfully carried out. A person who already has a cancer is strongly predisposed to receive transplanted cancer. Nevertheless, we have no right to regard cancer as a true contagious disease. When we observe an instance even of a successful transplantation of cancer, we are not justified in stating this as an evidence of contagion; it is merely a successful transplantation of the tissue. The author tells us that metastases are very frequent in bone and are very rare in the spleen. The blood-changes of carcinoma are practically the same as those in fever. The strongest predisposing cause of cancer is prolonged irritation, and this is especially true in those beyond middle life. Tilmanns dwells on the statistics of Williams, which exhibit the advancing increase of death-rate from cancer, especially in England, in which country the death-rate is 4 times greater than it was 4 years ago. [The question of the transmissibility of cancer is debated in the *Year-Book* for 1896.]

White[1] has employed **thyroid extract in treating cicatricial keloid.** The case in which he used it had been unimproved by other plans of treatment. There had been used upon it ordinary salves, sorbefacient oint-

[1] Univ. Med. Mag., 1895, vii. p. 812.

ments, pressure, and the internal administration of potassium iodid. White gave the thyroid extract in 5-grain tablets, administering from 2 to 4 of these daily, and applied collodion locally. At the end of 6 weeks the scar had reached the level of the adjacent skin and the hardness at the base had disappeared. [In the out-patient department of Jefferson College Hospital 2 cases were recently cured by collodion alone. In several cases thyroid extract was employed without apparent advantage.]

Wharton[1] discusses the **treatment of nevus,** and concludes that small capillary nevi are best treated by the application of pure nitric acid or by excision. For portwine marks he advises multiple scarification or electrolysis. In venous nevi he performs excision whenever possible, but if this operation is impossible he advises ligation or the actual cautery or electrolysis.

Sutton[2] reports a case in which he excised the upper half of the fibula for the cure of a sarcoma of that bone. He tells us that sarcoma of the femur or humerus is the most malignant tumor known, and is three times more deadly than a histologically identical sarcoma which arises from the bones of the leg or the foot. In view of these facts he thinks it is a very severe measure to amputate the leg for a sarcoma of the fibula. He concludes that the scarcity of records shows that periosteal sarcoma of the fibula is neither a common nor a very malignant tumor. Sutton says that a surgeon may be in active practice for a quarter of a century in a hospital situated in a large town and not be confronted with more than 3 examples of this condition.

Subtendinous exostosis is discussed by Brackett,[3] who reports a case. The tumor was taken away with a chisel, which procedure laid bare cancellous tissue. Examination of this tumor showed it to be what is known as exostosis cartilagina. The result was cure. Brackett says that the situation of the growth was such that whenever the patient attempted to walk it produced mechanical irritation of the tendon. These cases clinically resemble bursitis, and may be accompanied by bursitis. This can be differentiated from pure bursitis by the fact that the swelling is lower down and is hard, and never entirely disappears either from rest or compression. The microscopic examination of this specimen indicates that it arose as a nonsuppurative bursitis or ulceration in periosteal thickening and new bone formation. [This case seems to have been Albert's disease, bursitis of the bursa between the olecranon and the Achilles tendon, and periostitis at the insertion of the tendo Achillis.]

Snow[4] presents a note on **Cystic Degeneration of the Mammæ,** with 3 cases of recurrence on the opposite side. Snow says that we often hear breast-tumors spoken of as simple cysts, but that simple cysts very rarely occur in women verging on middle age, though in the young a dilated milk-duct is often seen, and may be thus designated. After the age of 34 cyst-formation is invariably due to general aberration in the evolution of the entire parenchyma of both mammæ. There may be found only a single cyst of sufficient size to appreciate, but with these are always associated numerous small

[1] Therap. Gaz., July 15, 1895.
[2] Brit. Med. Jour., May 2, 1896.
[3] Bost. M. and S. Jour., Jan. 9, 1896.
[4] Lancet, Nov. 16, 1895.

cysts uniformly distributed throughout the gland. If the case is not operated upon, the entire mamma will become a mass of cysts in which sooner or later intracystic vegetations, carcinomatous or sarcomatous, will develop. These cysts are caused by any emotional or mechanical hindrance to the physiologic processes by which the glands pass to their obsolete condition. If between the cysts there is excessive formation of white fibrous tissue, we speak of the condition as cystic fibroma. The operation should consist in the removal of the whole breast-tissue, and the surgeon should give a guarded prognosis as far as concerns the appearances of the disease in the remaining organ. He reports 3 cases in which after removal it recurred on the opposite side.

DISEASES OF THE ABDOMEN.

THE STOMACH.

Weir and Foote[1] have published an elaborate paper upon "The Surgical Treatment of **Round Ulcer of the Stomach** and its Sequelæ, with an Account of a Case Successfully Treated by Laparotomy." The authors state that gastric ulcer is one of the commonest of diseases, it having been estimated that of the population of Europe 4 or 5% labor under it. Some have estimated as high as 13%, and Fiedler, who examined postmortem 2200 stomachs, found ulceration or its scar in 20% of the women and 1½% of the men. Recent investigations do not sustain the statement that most ulcers occur on the posterior wall and lesser curvature. Ewald says that ulcer forms especially in the greater curvature and in the pyloric region, that part of the stomach which sustains the impact of irritating food, and also that part which hangs lowest when the patient is upright, and in which stomach contents therefore collect. The ulcer is usually single, but two or more may be present, and Orth says that in 20% of the patients with gastric ulcer more than one ulcer is present. This fact has an important bearing upon the surgical treatment of nonperforating ulcers. The great majority of cases of gastric ulcer are successfully treated by rest in bed, appropriate diet, with perhaps rectal feeding for a time, sedatives and laxatives, followed by tonics. But in some cases these measures fail to relieve the symptoms, and in others complications arise, notably perforation, hemorrhage, and violent gastralgia. In still others the ulcer or its scar obstructs the pylorus or causes adhesions between the stomach and adjacent structures. In such cases we must consider the measures of operative relief, and operation is most imperative when an ulcer is perforating or has perforated. Comte has estimated that perforation occurs in about 14% of cases of nonmalignant gastric ulcer, and that when it does take place it is almost invariably fatal. Barling says that 95% of patients after perforation certainly die without operation is done, and among the 5% of reported recoveries are some in which there is decided doubt about the diagnosis. When perforation does take place 1 of 3 conditions obtains: A general peritonitis because the stomach-contents have escaped into the peri-

[1] Med. News, Apr. 25, 1896.

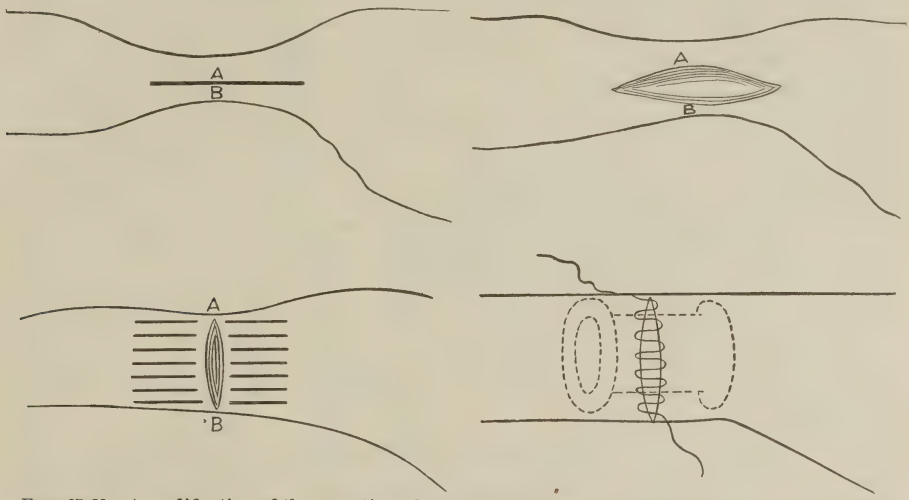
toneal cavity, the adhesions having been scanty. This condition is the usual one in anterior perforations, because in anterior perforations adhesions rarely form on account of the mobility of the anterior stomach wall and the adjacent viscera. In the second condition, which may possibly arise, there are some adhesions and the abdominal contents slowly escape. In these cases there is localized peritonitis which may advance to an abscess, or the barriers of lymph may give way and a general peritonitis may follow. If the perforation presents posteriorly, the lesser peritoneum may become involved and subphrenic abscess form. In rare cases it happens that an adherent perforation produces an abscess of the liver. The third condition which may arise is adhesion of the stomach and discharge of its contents into a hollow organ. This is, however, a very unusual complication. When perforation occurs into the general peritoneal cavity the case is desperate, although there are some dozen cases on record in which recovery has taken place without operation after undoubted perforation, and in some of these cases evidences of healed perforations have been found at subsequent autopsies. Pariser has collected 14 well-authenticated cases, but rest and rectal feeding offer so slender a hope of recovery that without the help of surgery the truth of Leube's statement becomes evident—that is, when perforation occurs the only treatment is to induce euthanasia.

In recent years surgical relief has been thought of as applicable. In 1883, Nelson C. Dobson lost a patient from gastric perforation, and the autopsy showed that the opening was on the anterior wall; and Dobson was impressed with the fact that it could have been reached surgically, and he advocated in similar cases operative interference. This idea had been held by others. In 1880, Mikulicz sewed up an opening in the lesser curvature of the stomach of a man. The patient died. His history was unknown, but it seemed probable that the perforation was not due to a recent ulcer, but to traumatism, a giving way of the site of the cicatricial ulcer. In 1885, and again in 1887, Czerny operated unsuccessfully for perforated ulcer. In 1889 Von Wahl, and in 1890 Mouisset, published each a fatal case, and in 1892 Weir published a fatal case. The first successful case was published by Kriege in 1892. Weir and Foote report a case in which recovery was uneventful.

Subphrenic abscess is an abscess arising from the perforation of a gastric ulcer, and is situated to the right or to the left or behind the stomach. This form of abscess can also arise from other than gastric lesions. It can come from disease of the gall-bladder, the liver, the spleen, the kidney, the duodenum, and the appendix. The pus may be extraperitoneal, which is rare, and is then commonly of renal origin, or it may occupy some portion of the lesser peritoneal cavity, or be limited to the space between the cardiac end of the stomach, diaphragm, and spleen or liver upon the right side. It rarely breaks into the general peritoneal cavity, but progresses slowly. It pushes up the diaphragm on the affected side, and frequently bursts into the pleural cavity or lung.

Maydl in his recent article in 1894 collected 10 cases of operation with 3

recoveries, and Comte found 13 others with 8 recoveries. Beck has had 3 successful cases, Abbe has had 2 fatal cases, and Weir 5 fatal cases, making, with McCosh's case, a total of 34 operations with 15 recoveries.



Weir and Foote then discuss the operations for nonperforating gastric ulcer and their sequelæ. These operations may become necessary because of adhesions, of pyloric stenosis, or of irregular gastric contractions. Sometimes ulcers in the pylorus may require to be resected, as in the case in which Keen removed from the lesser curvature a gastric ulcer. These points have been elaborately dealt with and the article is worthy of careful reading. [The first successful operation for gastric ulcer was performed by Rydygier in 1881, and the second by Czerny in 1882 (Greig Smith). In ulcers which cause considerable pyloric obstruction Doyen of Rheims advises the performance of gastroenterostomy. Both Curtis and Doyen have performed pyloroplasty for the same condition. Mr. Paul[1] expresses the following views as to the causes of failure after operation, and as to the best means to secure success. Failure may be due to collapse, imperfect cleansing of peritoneum, or leakage at suture line. In order to avoid collapse operate in stage of reaction before the development of marked peritonitis, and do the operation as quickly as possible. Cleanse by flushing with a large amount of water at a temperature of 100° F. Do not drain unless peritonitis has begun. Leakage may be due to the inaccessible situation of the ulcer. If it is found impossible to securely suture, it may be well to drain the stomach by a temporary gastrostomy. In some cases we can incise the anterior wall of the stomach, suture an ulcer on the posterior wall from within the stomach, and then close the incision in the anterior wall. Greig Smith's discussion of this subject in the fifth edition of his work upon Abdominal Surgery is altogether admirable. We advise the reader to consult it for full information.]

A. W. Mayo Robson[2] advises a **modification** of the usual operation **of pyloroplasty** for stricture of the pylorus. The principle of the operation of pyloroplasty is to obtain increased caliber by longitudinal incision and transverse suture. The operation was devised by Heineke in March of 1886, and a second operation was performed by Mikulicz in January of 1887; hence the procedure is often known as the Heineke-Mikulicz operation. Robson believes that pyloroplasty will completely replace Loreta's operation of divulsion, for there is less immediate risk and a far better prospect of freedom from relapse. He modifies the operation by the use of a bone-bobbin. By the use of the decalcified bone-bobbin only 2 continuous sutures are required—the first to unite the mucous margins, the second the serous edges. The bone-tube at once secures a thoroughly patent channel, and protects the line of sutures for from 24 to 48 hours, when union should be established.

Robson then reports a case to exhibit the value of the method. He says it can be done very quickly, with little exposure of the viscera, and that post-operative shock need hardly be feared, as the incision through the pylorus is through cicatricial tissue, and there is little or no fear of hemorrhage. In the

[1] Medico-Chir. Jour., No. 29, 1895. [2] Brit. Med. Jour., July 20, 1895.

2 cases he reports not a single ligature was applied. The only difficulty is that the pylorus has to be separated from the adhesions set up by the inflammation which caused the stricture. They are better separated by the fingers than by a cutting instrument. The longitudinal incision should be made in the lower margin, so that when the slit is sutured transversely the upper angle is well within view. He uses fine catgut to unite the mucous margin and fine silk for the serous surfaces. He has found the same operation very satisfactory in simple stricture of the intestines. The annexed cuts make clear this method (Figs. 27–30).

FIGS. 27–30.—A modification of the operation of pyloroplasty (Robson, in Brit. Med. Jour., July 20, 1895).

Paci[1] records a case of **intractable vomiting** which seriously endangered the life of the individual. Celiotomy was performed, and a stenosis of the pylorus was discovered, due to a perforating ulcer. The Heineke operation was performed and the patient made a thorough recovery.

Quénu[2] gives his views upon the **surgical treatment of carcinoma of the stomach.** He concludes that if the cancer is diffuse, if it is very adherent, if it involves many lymphatic glands, the surgeon should simply attempt palliation and should perform gastroenterostomy. If the cancer is operable, he advises the performance of gastroenterostomy, followed in 8 or 10 days by pylorectomy. He believes in a preliminary gastroenterostomy to enable us to build up the patient's strength before the more serious operation, and he thinks that the secondary pylorectomy can be done more rapidly than could a primary case.

C. H. Golding-Bird[3] of Guy's Hospital furnishes a note upon the **after-treatment of gastrostomy** cases. He says that the great trouble which attaches to the after-treatment of these cases is the tendency to leak, and this leakage of the stomach-contents digests the skin around the opening. His

[1] Il Policlinico, Oct., 1895. [2] Rev. de Chir., No. 10, 1895.
[3] Brit. Med. Jour., Jan. 4, 1896.

plan is as follows: He attaches the stomach to the abdominal parietes, and at the end of the 4th day after this operation opens the stomach just sufficiently to admit a No. 10 catheter, and then dilates this opening with laminaria tents until it is possible to introduce a short rubber tube the thickness of the fore finger. This tube is tied in situ, and the stomach-walls contract firmly around the tube and absolutely prevent leakage. The tube just projects into the stomach and reaches about 1 in. externally. It is kept corked, and the cork is removed at meal-times, when the patient is fed through a funnel and a temporary tube that will pass through the lumen of the permanent tube. The skin about the tube is smeared with boracic acid ointment which contains a large quantity of chalk. This preparation will counteract any acidity should regurgitation happen at any time. Golding-Bird says that if we make the opening in the stomach with a knife and at once insert a large tube, the subsequent contraction will grip the tube, but will not prevent leakage, for there is only cicatricial contraction to rely on; but if the opening is made by dilatation, the gastric muscle remains uninjured and acts like a sphincter around the tube, and this gives us an active as well as a passive hold. [Frank's method, it is asserted, gives most satisfactory results (see *Year-Book* for 1896). The fistula does not tend to dilate, as it does in other methods, and there is no leakage. Linderer, who has performed it 9 times, thinks it preferable to all other plans. Witzel's method is excellent, and is not followed by leakage. Golding-Bird's method impresses us somewhat favorably, and we will try it when opportunity presents.

Mr. Harrison Cripps[1] thinks that the chief trouble after a gastrostomy is leakage. He has devised the following plan to prevent it: "A circular disk of sheet india-rubber the thickness of a shilling is cut. Its diameter should be nearly double that of the orifice to be closed. A thread of No. 4 silk is passed by a needle a little to one side of the centre of the disk, and is passed back again, coming out a little distance from the original puncture and on the same side (see Fig. 31, *B*). The two ends of the thread are now parallel to each other, and should be left 6 inches long. The india-rubber disk is now folded into a circular roll and kept in this position by a fine pair of dressing forceps (Fig. 31, *A*). The roll is thus introduced lengthways through the orifice into the interior of the bowel or stomach, and when released from the forceps immediately expands to its original circular form. By drawing up the two strings the disk is lifted up against the mucous surface, and in this way effectually stops anything coming through. Indeed, the greater the pressure of the fluid within, the firmer is the disk pressed against the mucous wall. A little roll of lint the thickness of a pencil and an inch long, stiffened with a pin or a piece of wire down the centre, is laid over the external opening between the two strings, which are then tied in a bow across it, with just sufficient firmness to press the roll well down on the skin (see Fig. 31, *C*). It requires some experience in each particular case to find the exact size and thickness of the disk required.

[1] Brit. Med. Jour., June 6, 1896.

"For feeding the patient or obtaining relief all that is necessary is to untie the bow, remove the lint roll, and then, holding the thread lightly, press back with the director the disk into the bowel. It can be at once drawn back again

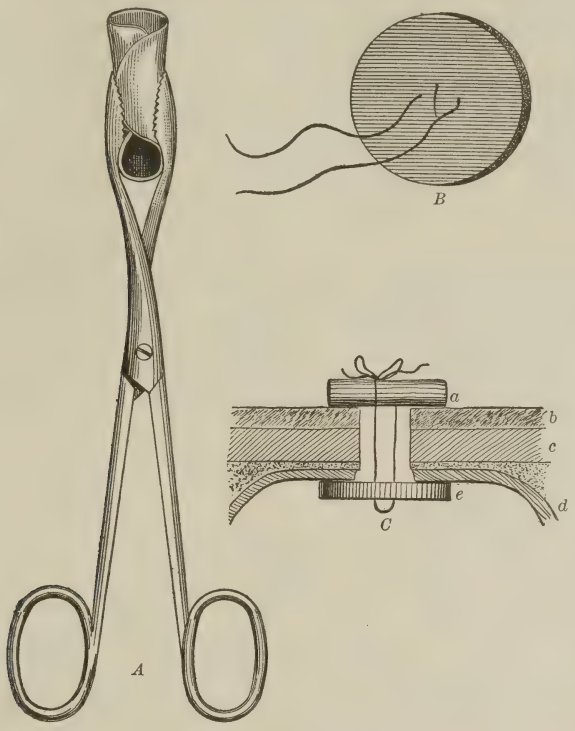


FIG. 31.—*A*, disk rolled up in forceps for introduction; *B*, disk with silk thread; *C*, disk and roll of lint in position: *a*, roll of lint; *b*, skin; *c*, abdominal walls; *d*, wall of bowel or stomach; *e*, disk in position (Cripps, in Brit. Med. Jour., June 6, 1896).

into position when required. I have found this method absolutely effectual in keeping the patients dry and clean."]

Galliard[1] reviews the subject of **pyloric obstruction from gall-stones,** and he reports several cases in which patients had vomited gall-stones or had passed them through the stomach-tube. In some cases the obstruction arises from an ulceration of the stones directly into the stomach-cavity after the formation of adhesions between the stomach and the gall-bladder. In some cases the gall-bladder becomes adherent to the pylorus, and the pylorus, being fixed to the gall-bladder, is immovable, and the stones which distend the gall-bladder diminish by pressure the lumen of the pylorus. In some cases the obstruction is due to the constriction of adhesions between the stomach and the gall-bladder. It is impossible to certainly diagnosticate such conditions except when gall-stones are obtained from the stomach by vomiting or by the use of a tube.

Francis S. Watson[2] of Boston reports an extremely interesting case in

[1] Am. Jour. of Med. Sci., Jan., 1896.

[2] Boston M. and S. Jour., Apr. 2, 1896.

which **hour-glass contraction of the stomach** followed the cicatrization of a gastric ulcer. He performed an operation by establishing an anastomosis between the cardiac and pyloric portions by a new method. The patient completely recovered and her health was entirely restored. Watson had expected to find cancer when he operated. The incision is shown in Figure 32. When he examined into the condition after the laparotomy, it seemed that gastroenterostomy, a plastic operation by longitudinal division and transverse suturing, and resection of the cicatrix were the only operations applicable (Figure 33 shows the condition of the parts). It seemed to him, however, that it would be better to establish an anastomosis between the upper and lower parts of the stomach instead of between the stomach and the intestine, and in this way to retain the useful function of the natural outlet of the stomach. He did not care to em-

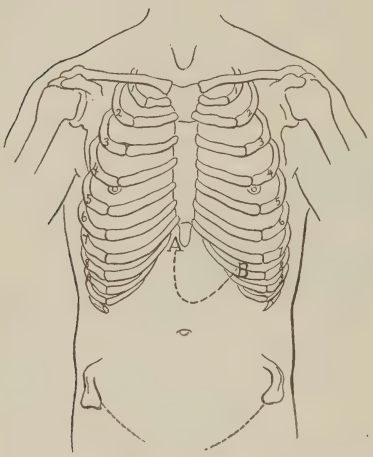

FIG. 32.—*A-B*, line of incision (Watson, in Boston M. and S. Jour., Apr. 2, 1896).

FIG. 33.—Showing position of stricture (Watson, in Boston M. and S. Jour., Apr. 2, 1896).

ploy the plastic operation, because of the great amount of cicatricial tissue present and the difficulty of securing a wide opening; resection of the cicatrix seemed to involve a great deal of danger, so he devised the operation herein indicated. The pyloric portion of the first part of the duodenum was lifted upward and turned over on the cardiac portion, the constricted part acting as a hinge, and was united to it by a single row of fine silk sutures in the form of an ellipse 4 in. in length and $1\frac{1}{2}$ in. in width. One suture was left long on either side of the end of the ellipse (Fig. 34). This complete junction of the two portions before making the incisions was done to avoid spilling any of the stomach-contents into the peritoneal cavity. He now made an incision into the upper part of the pyloric portion in order to gain access to the sutured surfaces. Through this opening he established communication 3 in. in length (Fig. 35). This allowed examination of the stricture from within the stomach. The constriction was very dense and barely admitted the little finger. The edges of the communicating incisions were sewed over so as to prevent their uniting (Fig. 36). The incision through the pyloric portion of the stomach was rapidly sutured, the stomach returned to the abdomen, and the abdominal wound completely closed. The patient was fed by nutrient enemata for the

first 5 days, and was then given liquids by the mouth. On the 10th day she was given solid food. On the 21st day she was eating heartily and out of bed. It is now 5 months since the operation. The patient has resumed her work; her gain in weight is 27 lbs. She is in excellent health. (Figure 37 shows the form of the sutured areas.)

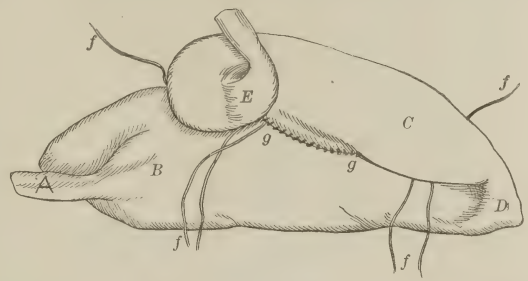

FIG. 34.—Showing the pyloric end laid upon the cardiac end of the stomach, and united by the ellipse of sutures, one side of which is shown (*f, f, f, f*); *g, g*, is the incision through which the interior of the pyloric part of the stomach was entered, after the two parts of the stomach were wholly united, in order to make the communicating incisions (Watson, in Boston M. and S. Jour., Apr. 2, 1896).

When Watson operated he was not aware that any operation like this had been done before, but he subsequently found that Wolf had performed a similar operation in 1894, and Eiselberg had also done it in the same year. Watson's case is therefore the third on record. The appended cuts exhibit the method of operating. [Weir and Foote in a paper previously noticed (p. 266) discuss the question of hour-glass stomach, and state that this condition "has three times been operated upon in substantially the same manner—viz. by establishing an anastomosis between the two halves of the stomach." Wölfler reported a successful case;[1] Watson reported a successful

Jour., Apr. 2, 1896).

with a Mikulicz-Heineke incision anteriorly, or "a double gastroenterostomy may be performed, tapping each sac of the stomach." (Weir and Foote refer to Von Hacker's "Magenoperationen," 1895).]

PERITONEUM.

Alexis Thomson[1] of the Edinburgh Royal Infirmary presents the surgical aspects of **peritoneal tuberculosis.** He tells us that it is a clinical fact that tubercular disease in the peritoneum is benefited by surgical exposure, but there are no anatomic and physiologic facts known to us which explain why this is true in the peritoneum, though not true in the pleura, synovial membranes, tendon sheaths, skin, and other organs and tissues. [The anatomy of the peritoneum does differ from that of other serous membranes. The lymphatics are present in greater number and have less regular channels (Morris).] Cases of tubercular peritonitis subjected to celiotomy have been recorded by many surgeons following different methods. Benefit has resulted whether the peritoneal cavity was irrigated or simply inspected, whether drainage had been used or not, whether iodoform or some other supposed antitubercular agent had been introduced or such procedure had been omitted. It was assumed by many that the removal of the ascitic fluid was the explanation of the cure of some of the cases, but this cannot be the essential factor, because there is but little improvement in cases which have simply been aspirated, because improvement has followed celiotomy where there was no fluid to evacuate, and because in cases in which surgeons had operated and found fluid circumscribed or encysted beyond reach recovery followed, although the fluid was permitted to remain in the abdomen. Some regard the admission of air into the peritoneal cavity as the curative agent, but it is improbable that this has any influence. Other theories have been set forth to explain these im-

[1] Practitioner, Nov., 1895.

provements—the escape of ptomains and toxins, the entrance of antagonistic organisms, the exposure of the peritoneum to sunlight, and the use of an anesthetic and the alteration of the intraabdominal pressure. Thomson believes that the incision itself is the one constant and essential factor in bringing about a cure. The benefit is due to the effects of the operation per se, and not to any particular method of operation. Tubercular peritonitis not infrequently terminates in spontaneous recovery. In the peritoneum the tissues and the bacilli seem to meet on more or less equal terms, and it requires only a little assistance to enable the tissues to obtain the upper hand. An incision may reinforce the tissues or stimulate their energies. There are many clinical evidences in favor of this view. Thomson has had 3 cases in male children in which there was tubercular disease in the patent vaginal process and in the general peritoneum, in which it was found that excision of the tubercular vaginal process or simple incision of the process was followed by cure of the peritoneal tuberculosis. Such cases have been reported by Harold Stiles and others and by Goldmann. The operation upon the vaginal process is analogous to laparotomy for tubercular peritonitis, both operations being followed by improvement which cured all the tubercles diffused throughout the peritoneum.

Thomson then cites a very remarkable case in which a large tubercular tumor involving the cecum entirely disappeared after an exploratory operation. The woman was supposed to be suffering from recurrent appendicitis, and there was a well-marked, firm, and movable tumor in the iliac fossa. Annandale, after opening the abdomen, discovered the cecum, which was firm and solid and crumpled, with the vermiform appendix fused to it posteriorly and inferiorly, and below the adjacent coils of ileum studded with miliary tubercles, with notable enlargement of the mesenteric glands. One of these glands was removed, and later examination proved it to be tubercular. The tumor of the cecum was not interfered with and the wound was closed. Nine months after the operation she was completely well and there was no trace whatever of a tumor. The disease in this case apparently involved all the coats of the infected segment of the intestine. It is a matter of congratulation that the affected portion of the bowel was not resected according to the routine practice of some operators. [Greig Smith recently discussed the spontaneous disappearance of abdominal tumors. (See *Year-Book* for 1896.)]

Thomson next recalls to our minds the fact that cases have been recorded by Greig Smith, Crawford Renton, and others in which exploratory celiotomy disclosed supposed inoperable tumors, which tumors afterward entirely disappeared. As, however, in these cases no microscopic examination was possible, they are less instructive than they would otherwise have been. Nannotti and Baciocchi have been endeavoring to determine the influence of the operation by experiments upon dogs and rabbits, and they express the opinion, as a result of these operations, that operative interference stimulates reparative changes by the mechanical influence which it exerts on the peritoneum. We may conclude from clinical experience and from experimental evidence that the

benefit which results from surgical interference in peritoneal tuberculosis is due to the abdominal incision and the manipulation of the parts.

Thomson reminds us that all cases of peritoneal tuberculosis should not be operated upon, as there is a natural tendency to spontaneous recovery; no cases should be operated upon until medical treatment has had a fair though a not too prolonged trial. Upon the local measures in which some confidence is to be placed he mentions massage of the belly and measures calculated to restore the normal functions of the intestine. The inunction of mercury and other ointments is chiefly beneficial because of the mechanical manipulations, which stimulate the tissue activities. The securing of copious evacuations of the bowels by drugs is also to be recommended. Should these means not soon produce amelioration, operation is to be thought of. In all cases of diffuse serous or purulent ascites operation is very certain to cure; free incision is made, the fluid is evacuated. When the fluid is serous we can, if we wish, insert some iodoform into the parts exposed by the incision and close the wound by suture. The iodoform is probably of value by preventing tubercular infection of the tissues of the abdominal wall and the consequent breaking down of the scar. It is not probable that it influences the existing peritoneal tuberculosis. When the fluid is purulent—that is, when cold abscess exists—we should drain with a tube for 2 or 3 days, removing the drainage-tube when the amount of discharge is no longer sufficient to soak the dressings. To leave the drainage-tube longer may lead to the development of a sinus or by pressure may favor the formation of a fecal fistula. Operation is remarkably successful when fluid is encysted or circumscribed by adhesion. When fluid is small in quantity and when adhesions constitute a predominant feature in the case, more knowledge is required in regard to diagnosis and as to the advisability of operation. Thomson has had 5 such cases, in all of which he operated at one stage or another—in 2 for the purpose of relieving obstruction of the bowels, in the remaining 3 with the object of curing the tubercular condition. In every case the diagnosis was much aided by a rectal bimanual examination made under anesthesia, for in every case such an examination detected a large swelling in the pouch of Douglas, which consisted of a mass of adherent intestinal coils. This matting of the intestines in the pouch of Douglas is one of the evidences of tubercular peritonitis. Matting is always more marked below the umbilicus than above it, and expresses the influence of gravity in the localization of infective intraperitoneal disease. The operations for obstruction were both successful. In the 3 remaining cases of matting and adhesion the operation was performed for the cure of a tuberculosis. All were males, their respective ages being 6, 15, and 37. In the first case a median laparotomy was done below the umbilicus, and the adherent coils beneath the abdominal wound were partially separated. It was followed by satisfactory recovery. Both of the other cases were less favorable, because they presented a suspicion of tubercular disease of the lung. In both of them an attempt was made to separate the adherent coils of intestine. In both fecal fistulæ formed at a subsequent date. In both there was for a time de-

cided improvement in the general condition, but the boy died 5 weeks after operation with a large empyema, and the man died 3 weeks after operation of pulmonary tuberculosis. In these cases a drainage-tube must on no account be employed. It has been shown by irrefutable evidence that perforation of the wall of the bowel is not the result of ulceration of the mucous membrane, but the result of the breaking down of a tubercular nodule on the peritoneal or external surface of the bowel. [I. Israel says that the cure of tubercular peritonitis by operation is not due to evacuation of fluid, for he has seen cases cured when no fluid was found. Most observers think high temperature contraindicates operation, but Israel does not think so. Spencer Wells has followed some cures for 25 years. Stchegoleff says recovery is brought about by inflammation; embryonic tissue forms and active phagocytosis takes place. Jordan says the cause of cure is unknown, but unquestionably the tubercular tissue is absorbed and the peritoneum returns to a normal condition, in many cases with formation of adhesions. Cure is not considered as attained until 1 year after operation. Roesch has collected 358 cases operated upon: 20 died from the operation, 51 died in a few weeks from tubercular disease in other regions; 250, or 70%, were cured. (See Beiträge zür klinische Chirurgie, Band xii. Heft 3, 1895).]

Louis Frank [1] in an article upon **septic peritonitis** maintains that the gonococcus in its virulent state, before it has been for any length of time in the pus of a pyosalpinx, is capable of producing virulent peritonitis, and he cites a case to prove it.

HERNIA.

Golding-Bird [2] discusses **the curability of hernia.** He tells us that hernia is the objective result of multiple hidden causes, not the least of which is the patient's habit or occupation. From its surgical-therapeutic point of view there are 2 forms of inguinal hernia—the congenital and the acquired; and of the former there are two varieties: one is the strictly congenital, when the gut enters a patent tunica vaginalis; the other is due to the gut making its way into a congenitally patent tunica vaginalis through the abdominal end of its vaginal process at the inner ring. He says that a truss acts not by corking up a hole, but by flat pressure preventing the exit through an abnormal aperture of some of the abdominal contents, and thus far it is palliative. It can be curative if it brings about closure of the aperture, and it may do this in one of two ways: In the congenital hernia of infants we are dealing with a condition of delayed development. If, therefore, in the earliest months of life we so adjust a truss that the gut never protrudes, natural closure will in many cases continue and come to a successful termination. The child is then cured by a truss. In later child-life and in young adult-life there is no tendency for this normal developmental process to go on. The aperture may physically contract, because it is never allowed to be stretched, yet there the aperture is. There will always be danger when a truss is removed unless

[1] Med. News, Oct. 19, 1895.

[2] The Practitioner, Jan., 1896.

some obliterative adhesions form or some viscus, as the omentum, becomes closely adherent across the mouth of the sac. Let us suppose a young man has been advised to wear a truss for hernia; after seven years he asks if he may leave it off, as he has seen no sign of a rupture for the past five years. What proof is there that he is cured in the sense of securing permanent closure, or that he is simply temporarily relieved by a contraction of the opening into the sac? There is no proof except trial. He may be cured for good, but the chances are against this, and the risk of waiting to see by leaving off the truss is hardly compensatory. Golding-Bird then quotes Macready that 58 % of cases under 12 months of age can be cured by a truss, 10 % of cases between 1 year and 5, and after that practically none; and in acquired hernia the truss cures at 15 years 5 %, and at 30 years 1 % of cases. He therefore lays it down as a rule that except for infants under 1 year of age we need not attempt to cure by a truss, and for the bulk of patients a truss once adjusted means a truss for life. In order to cure a hernia the surgeon must put some opposition to its exit, or so alter the peritoneum that not only is the sac removed, but the funnel-like peritoneal depression is removed also. The old methods of radical cure consisted in the production of plastic inflammation about the neck of the sac, and more lately in the sewing of the stump of omentum in the neck of the sac. Both of these means are absolutely unreliable. We have learned from these procedures that it is not so much the occlusion of the passage we desire as the alteration of the face of the peritoneum, thus preventing the impulse of the gut at the same spot and leading to the obliteration of the sac. [We have had better results from the methods of Bassini and Halsted than from any other procedures. The closure should be effected with kangaroo tendon, a material which is not absorbed for 60 days.]

Schloffer[1] has made **bacteriologic examinations of hernial fluid** with reference to attacks of pneumonia complicating strangulated hernias. His conclusions were that the fluid taken from hernia in human beings was sterile. In animals bacteria were found after a period of incarceration of 7 hours, but bacteria were sometimes absent in animals even after an incarceration of several days. Fluid containing bacteria was sometimes found round a loop of intestine which was functionally active, and sterile fluid was occasionally found around a loop of intestine whose nutrition was almost destroyed. If bacteria once appeared, they progressively increased in number during the incarceration. The fluid at first is bactericidal in its properties, but this is gradually destroyed. In human beings the diplococcus of pneumonia may pass from the intestines into the fluid of the hernia, and this would prove the connection between strangulation and the pneumonia which sometimes is associated with or follows it. The author believes that such pneumonia is due to septic emboli.

How to prevent hernia after celiotomy was discussed at the Congress of Gynecologists in Vienna. Winters[2] showed that in his clinic after

[1] Beiträge z. klin. Chir., 1896, xiv. No. 3, p. 813. [2] Wien. klin. Rund., 1895, p. 569.

celiotomy he had 30% of hernias in 1889 and 23% in 1891. The prevention of these herniæ depends on securing primary union of the wound, and in suturing each layer of fascia instead of including all layers in one suture, Winters now follows this method and uses catgut sutures, and during 1884 reduced his postceliotomy hernias to 8%. He uses collodion to dress his wounds, and never employs a binder.

Bollini[1] reports an extremely interesting **case of a reducible hernia** which occurred in the left ischiorectal fossa, the hernial mass being about the size of a cocoanut. Prof. Bollini performed an operation for the relief of this condition. He placed the patient in the lithotomy-position, and made an incision parallel to the ascending ramus of the ischium. He removed the fat from the ischiorectal fossa, separated the fibers of the levator ani, and opened the peritoneum. The sac was found to contain the left tube and ovary, a portion of the sigmoid flexure, and a loop of small intestine. Catgut sutures were employed to close the wound, the tissues about the vagina and rectum and the internal obturator aponeurosis being approximated. Perfect cure was obtained.

Croly[2] upon **hernia and taxis** says that taxis should mean the methodical and the gentle manipulation of herniæ for the purpose of effecting their reduction—never forcible manipulation, by which tissues are contused and often irreparably damaged. More injury may be inflicted on the bowel in a few minutes by brute-force taxis than the constriction could produce of itself in several days. He quotes the old rule of Desault, "to think favorably of a strangulated hernia when taxis has not been used," and modifies this surgical aphorism thus: "Think favorably of a strangulated hernia when the taxis has not been abused." If there are signs of inflammation or edema, of emphysema or gangrene, or if the patient is in collapse, never employ taxis. If the tumor is very tense, especially in the femoral region, the less taxis the better. Croly's own practice has for many years been as follows: Having satisfied himself that the case is one of strangulation, he has the bladder emptied and an enema administered by means of a long tube. He has the patient anesthetized and all instruments and appliances ready for operation. In the suitable cases he gives the taxis a fair trial, having the parts relaxed by proper position, and, if no impression can be made on the tumor, proceeds at once to operate. He ventures to try the taxis longer in an inguinal hernia than in a femoral hernia. He has seen the intestine in a femoral hernia burst by the efforts of a patient to reduce it. He has seen a femoral hernia reduced en masse by taxis with inversion of the body. Dangerous as taxis is in unskilled hands, it is often the cause of death in experienced hands by the dangerous delay in operating. We commend the rest of this article to the attention of the reader.

Two very remarkable cases of **obturator hernia,** one of which was bilateral, are reported by Anderson,[3] who says that this is one of the rarest of sur-

[1] La Clin. Chir., Aug., 1895. [2] Dublin J. M. S., July 1, 1895.

[3] Lancet, Apr. 4, 1896.

gical maladies. Only 30 operations have been known to be performed for this condition in Europe down to the present time. Case 1 is the only example reported of bilateral obturator hernia treated by operation. Case 2 shows the disastrous consequences of delay in calling for the surgeon's aid in obscure conditions of intestinal obstruction. Case 1 was a woman of 70 years of age. She had suffered for the last 7 years from occasional attacks of intestinal obstruction, accompanied by pain on the inner side of the left thigh and some fulness in Scarpa's triangle. The symptoms always disappeared in the course of a day or two and left no ill effect.

In a discussion on **the treatment of hernia in children**[1] Rushton Parker said that there is presumed to be the employment of a truss in the first instance, and in not a few instances the hernia entirely disappears. Phimosis by the straining which it occasions is thought sometimes to be contributory to hernia, and this condition should always be relieved by circumcision when the truss is used. If we perform a radical cure and phimosis exists, we should circumcise at the same time or shortly afterward. The recent improvements in the operation for radical cure have led us to a certain extent to relax efforts with trusses. Parker, however, still maintains that when a truss satisfactorily keeps up a hernia no surgical interference is necessary, and there is no doubt that well-trussed herniæ in children have a strong tendency to become cured. Parker has operated on 40 cases by the radical cure, and there have been only 2 failures. The operation in children is easier than it is in adults in most cases, but occasionally it is rendered difficult by the small size of the parts concerned and by the close attachment of the sac. As a rule, the sac should be opened. No object is served in refraining from opening it. Ligature of the neck of the sac often brings about a cure, but Parker believes that Macewen's method is the most rational and secure. In the case of infants in arms the patient is kept under observation until healing is accomplished, which is about a week or so. In older cases the patient is kept in bed for several weeks to ensure a firm resisting scar. Macewen has advised a period of recumbency of 6 weeks in adult operations. In active children of from 6 to 12 the same rule should be enforced, while in younger children yet in arms it is carried out, though to a less prolonged extent. In double hernia we may do both the operations the same day. In the discussion which followed, Mr. Lockwood said that he avoided operations in infants because they might be cured by trusses and because there were certain anatomical difficulties and dangers. It is always difficult to separate the sac from the spermatic cord without injuring the cord. The operation for inguinal hernia in little girls was very easy. At first Lockwood used to do Macewen's operation; now he opens the canal boldly, in order to be sure that he has stripped up the sac as far as the internal ring. In regard to the allegation that the aponeurosis of the external oblique is not a firm support, he had never met with a case of failure from this cause. He employed twisted silk as a suture material. Mr. Langdon said that he had never yet met with

[1] Brit. Med. Jour., Sept. 21, 1895.

a child who could not wear a truss. If it was not comfortable, the fault lay with those who adjusted the truss. In 100 cases in private practice 47 were cured during the first 3 years, and there were only 8 in which treatment by truss was not satisfactory. Cases of hydrocele were not suitable for treatment by truss. Adherent omentum with fluid necessitates operation. Large herniæ, even when well kept up by a truss, may occasion so much discomfort as to demand operation. Macewen said that treatment by a truss, however possible in private practice, was impracticable among hospital out-patients. He had operated upon some 20 or 30 children in which there had been great difficulty in keeping up the sac by a truss. He admitted that there was some difficulty in separating the cord from the sac, and also that the conjoined tendon was thin, but these tissues, though delicate in children, were reliable and better to depend on than cicatrix. He also uses catgut, and claims that it remains unabsorbed for 2 or 3 weeks. He never uses drainage and never had suppuration. Cousins said that he preferred to operate at the age of 1 year or over, provided the child was in good health and every exciting cause had been removed. He seldom operated on children under 1 year. Some cases are cured by careful truss-treatment, but many parents among the poorer classes cannot carry it out, and a few cases are quite unsuitable because of the size of the protrusion or the difficulty of keeping it up. He believed in all congenital herniæ the sac should be completely divided—that we should form a new tunica vaginalis and secure the sac firmly within the canal. Since 1890 he had performed 90 operations. Three had died—1 from scarlet fever, 1 from measles and bronchitis, 1 from acute septicemia contracted by careless nursing; but the other cases had been completely successful. He always employs a specially trained nurse, and carefully covers the seat of operation with india-rubber traction, and insists upon rest after the operation in the recumbent posture for some weeks.

Macready said that the proper classification of hernias was into those controllable by trusses and those uncontrollable. If we extend the practice of operation to include controllable cases, we may obtain flattering results, but overstep the bounds of necessity. Many cases are cured spontaneously or by trusses. The danger of strangulation in childhood is infinitesimal. He prefers to postpone operation at any rate until after puberty. Southam said that when we treat a patient by a truss we should carefully regulate the diet. In infants under 9 months old a Berlin wool truss is sufficient. After the child begins to walk a strong truss is the best. After a fair trial of a truss, and when there is no tendency to spontaneous cure, we should operate. Symonds said he only operated when truss-treatment failed. He employed Macewen's operation, and used catgut sutures and drained for 48 hours. Lucy agreed that diet was an important consideration—that all straining should be prevented, that phimosis should be treated by circumcision, and that any congenital smallness of the meatus should be corrected. Harrisson claimed that the simpler the operation the better, and, as children's tissues stand sutures badly, the minimum quantity will do. Waterhouse was surprised at the way every

speaker had excluded strangulation. He had himself operated 4 times for strangulated hernia in children under 2 years of age, and had assisted in 2 or 3 others. He employs Macewen's operation and the recumbent position for 6 weeks for even young children. Morgan said that in recent years he had seen a great many cases of strangulated hernia in children. He preferred to do a radical cure when the child was more than a year old, because of the difficulty in separating the sac from surrounding parts. He found that none of the suture-material in general use was quite satisfactory. Parker in replying said that the green sulphurized and chromicized catgut was perfectly satisfactory for sutures. It is strong and takes several weeks to absorb. He never uses the common yellow catgut except for the skin. With regard to recumbency, he considers infants in arms sufficiently recumbent. Older children should be kept for some time in bed after the operation. He thought it better not to open the inguinal canal. He generally, though not always, sutured the pillars of the ring, and agreed with Cousins that in children even an imperfect operation often succeeds.

Brown[1] has reported **a case of strangulated hernia** in the right inguinal region in a child 2 months old. Inversion and taxis under chloroform failed to bring about reduction. The index finger of the right hand was introduced into the rectum and steady pressure was made on the mass externally with the left hand. With the finger in the bowel he pushed the part of the mass which could be felt through the abdominal opening from side to side. By this maneuver the mass was moved back through the opening and finally dropped back into the abdomen, when he found that the tip of the finger could then be inserted into the internal ring. He suggests that a surgeon with a small hand might introduce the hand into the rectum and carry out this maneuver in adults.

Henggeler[2] gives a study of the **statistical results** of 276 cases of strangulated hernia. There were 64 deaths, with a mortality of 23.2%. He excludes 3 deaths in cases not operated upon, 13 in which it was necessary to make an artificial anus, 8 in which resection of the intestine was necessary, and 7 others in which the conditions were very complicated. These exclusions left a mortality of 15.5% for the ordinary operation of strangulated hernia.

Rose[3] showed **2 unusual cases of hernia.** In 1 there was an irreducible femoral epiplocele which became strangulated, and when seen and admitted gangrene of the hernial contents and adjacent skin was present with marked toxemic symptoms. There was a large black slough protruding through an oval aperture in the skin about 2 in. in diameter, and it had the characteristic appearance of dead omentum. There was no escape of feces and no general abdominal distention or tenderness. The wound was dusted with iodoform and charcoal poultices were applied. The bowels were not opened until the third day. The slough separated, the wound healed, and the patient made a thorough recovery. [Dr. Hearn recently attended a similar case in

[1] Med. News, May 4, 1895.

[2] Beiträge z. klin. Chir., xv., No. 1, p. 1.

[3] Lancet, June 20, 1896.

the Jefferson College Hospital.] The other case showed that a chronic process of inflammation had been going on for years between the sac-wall of a femoral hernia and the reducible portion of omentum surrounding a prolapsed varicocele, leading finally to a complete shutting off of these structures from the peritoneal cavity. Mr. Rose on operating found a great mass of sclerosed omentum. It was completely shut off from the general peritoneal cavity, and running through the center of it was the appendix; this and a mass of omentum were removed on a level with the femoral opening and the wound healed in a few days.

Lockwood[1] considered the operation for **strangulated inguinal hernia** in relation to recent advances in surgery. The operation which he performs differs in many ways from that which used to be done. It is simply the operation for the radical cure of inguinal hernia, but differs from Ferguson's old operation. The objects aimed at are not only to relieve the strangulation, but also to cure the hernia. No special instruments are needed except a pair of curved blunt needles for transfixing the sac or omentum and for restoring the inguinal canal. The other instruments are such as would be ordinarily necessary in a hernia operation, although a director and hernia knife are not required, because the neck of the sac is divided from the outside. When the operation for strangulated umbilical hernia is done the same instruments are necessary. A broad-grooved director and herniotomy knife are still necessary for the operation upon strangulated femoral hernia.

Robson[2] describes a case of **enormous hernia treated by operation.** The man stood 6 ft. and the tumor reached to his knees. He was 62 years of age and had emphysema and a winter-cough. The left hernia was first operated on. The greatest difficulties consisted in returning the contents of the sac. It seemed to contain a great part of the intestines, and it was necessary to remove a large amount of omentum. It was impossible to encircle the neck of the sac with one ligature, and it was treated with interrupted sutures as in closing the incision of the ordinary celiotomy. The aponeurotic and muscular layers were then sutured separately—the latter by ordinary interrupted silk sutures, the former so as to bring surfaces of the aponeurotic surfaces together. The skin was sutured by silkworm gut, and a large cavity in the cord was drained. Healing took place, and in October he had the other side operated on. The herniæ were completely relieved. It is probable that in the future such large herniæ will rarely be seen, since ruptures which cannot be restrained by truss will be operated upon at an earlier period. The method Robson usually follows is to lay open the inguinal canal to ligate the neck of the sac, and to excise the sac $\frac{1}{2}$ in. below the ligature. In order to carry the pedicle inside the abdominal muscles he leaves the ends of the encircling ligature long, threads them on curved needles, carries them behind the transversalis fascia, makes them pierce the whole thickness of the abdominal wall, and thus leaves no pouch opposite the internal ring. The layers of the abdominal wall are sewn up separately, the cord is freed as in Bassini's or

[1] Lancet, Mar. 28, 1896.

[2] The Practitioner, Oct., 1895.

Halsted's operation, and if there is redundancy of the spermatic veins they are excised. Drainage is only employed where a large cavity is left. The patient rests for about a month, and no truss need subsequently be worn.

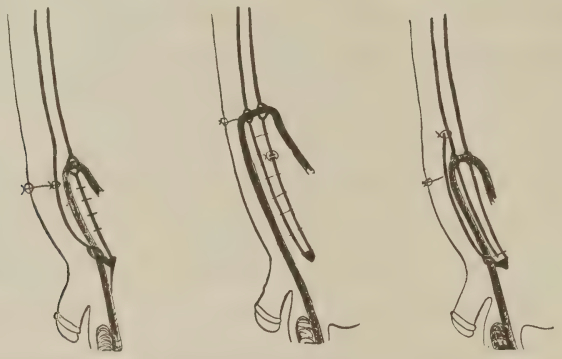

FIG. 38.—Schematic representation of anterior abdominal wall in anterior posterior section, showing 3 methods of disposal of the cord (Andrews, in Chicago Med. Recorder, Aug., 1895).

Imbrication or lap-joint method, a plastic operation for hernia, is the title of an article by Edward Wyllys Andrews[1] of Chicago. He advocates the overlapping the several aponeurotic layers of the abdominal wall. The present paper deals with inguinal hernia. He uses this method to supplement and reinforce existing methods. The principle is the outgrowth of clinical experience rather than theory. Every operator who has done many Bassini operations will corroborate the statement that occasionally quite an undesirable degree of tension comes upon the deep sutures. It is often difficult to close the internal ring without dragging upon Poupart's ligament. In very large rings there is such an absence of conjoined tendon on the inner and upper margin that instead of finding good aponeurosis or muscle to stitch to, we find that we must go quite to the sheath of the rectus. The appended cuts will exhibit the principles of this operation (Figs. 38–41).

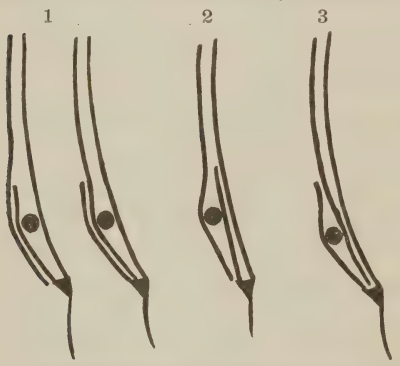

FIG. 39.—Diagram of 3 possible methods of imbricating the layers of the abdominal wall (Andrews, in Chicago Med. Recorder, Aug., 1895).

Coley[2] writes on **the Disadvantages of Nonabsorbable Sutures** in Operations for the Radical Cure of Hernia. In 1893, in a paper written by Dr. Bull and himself, the statement was made that we should discard all methods in which foreign bodies, even though aseptic silk and silver wire, were buried in the wound of a hernia-operation. Since that time there is an accumulated mass of clinical evidence in support of this view. Coley has added 14 observations in which, when these sutures were used, sinuses subse-

[1] Chicago Med. Recorder, Aug., 1895.

[2] N. Y. Med. Jour., Feb. 29, 1896.

quently formed and relapse of the hernia took place. In 250 operations in which he has used kangaroo tendon for buried suture he has not found a single case of sinus formation, and has had 96% of primary unions. When a sinus does form after using nonabsorbable sutures, it is the least of the evils, for in nearly all reported cases the suppuration so weakens the tissues

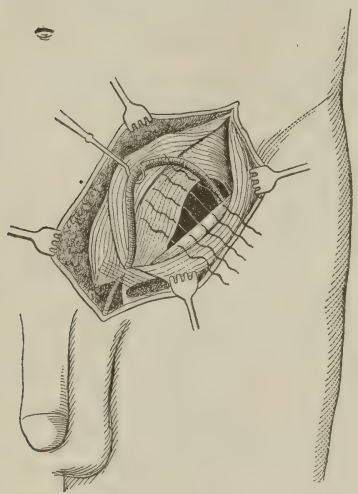

FIG. 40.—Bassini's operation, showing deep sutures ready for tying to repair internal ring (Andrews, in Chicago Med. Recorder, Aug., 1895).

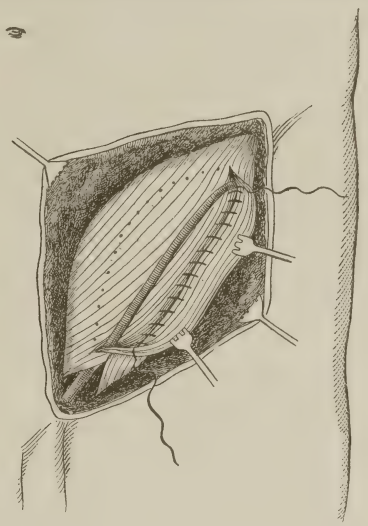

FIG. 41.—Imbrication operation, showing how the deep sutures draw upper flap of external oblique down to Poupart's ligament. The lower flap shown retracted will be replaced over cord to the dotted line (Andrews, in Chicago Med. Recorder, Aug., 1895).

that relapse follows. Every abdominal surgeon knows that silk sutures, even if buried within the abdominal cavity, frequently find their way out. The presence of sutures in the hernial canal after firm union results in harm and not in benefit, for even the firm tendinous structures that make up the walls of the hernial canal require no more than 8 or 10 weeks for firm union. The ideal suture is one which would hold the parts in apposition for this length of time and then be absorbed. The kangaroo tendon fulfils these conditions. Unless those who use and advocate silkworm gut or silver wire in hernia operations are able to present some advantages to offset the serious disadvantages that have been demonstrated, nonabsorbable sutures should be entirely abandoned. [We are in entire accord with Coley in his contention.]

Brewer[1] makes a report on the condition of the parts found upon autopsy 6 weeks after **Bassini's operation** for hernia. The patient had been stricken with apoplexy 5 weeks after operation, and died 7 days after his apoplectic seizure.

"The skin and subcutaneous areolar tissue were found to be moderately adherent to the aponeurosis of the external oblique muscle. The divided aponeurosis had firmly united throughout. At the upper extremity of the wound a portion of the fine silkworm

[1] Am. Med. Surg. Bull., Feb. 29, 1896.

gut was seen imbedded in the tissues in an apparently aseptic condition. The floor of the inguinal canal was found to be firm. The arched border of the internal oblique and transversalis muscles apparently united with Poupart's ligament. Between the aponeurosis of the external oblique and the floor of the canal the vas deferens, spermatic artery, and a number of veins could be seen, apparently healthy and lying separately. These were traced upward through the artificially made internal ring and downward into the scrotum, becoming more united and apparently bound together as they approached the testicle. None of the kangaroo-tendon sutures could be found, although several small tendinous shreds were imbedded in the tissues."

De Garmo [1] furnishes a note upon **the surgical cure of hernia.** He says that we occasionally find in the canal when we perform Bassini's operation substances that must be removed, and which if left behind will strongly predispose to relapse. These substances are tough and thick sacs, constituting a noncollapsible serous tube connected with the cord, extraperitoneal lipomata, enlarged veins connected with the cord, and masses of adherent omentum. He states that any method of operation which fails to remove all abnormal tissue will be a failure. He holds that suture material shall not be such as will readily absorb, that the mortality is a fraction of 1%, and that the time of confinement to bed should be but 8 or 10 days. The percentage of permanent cures is about 90. [If we want a permanent cure, we should keep a patient in bed for 4 weeks after operation. What we must get is a tendinous union, and we cannot get this solidly in less time.]

Cabot [2] says in regard to the operations for the **cure of inguinal and femoral hernia** that we should make a new canal, running upward and outward, so that the downward pressure of the bowels coming at right angles to the axis of the canal would tend to force its walls together. We may accomplish this by keeping the external oblique aponeurosis well up toward the anterior superior iliac spine, as in Bassini's operation, cutting off the sac on a level with the surface of the peritoneum, then suturing the internal oblique and transversalis fascia on the inner side and Poupart's ligament on the outer side, which sutures include the edges of the slit in the external oblique aponeurosis, thus closing the old inguinal canal. The upper portion of the cut in the external oblique aponeurosis is closed with a continuous buried suture, which also includes the upper edge of Poupart's ligament. The spermatic cord is brought through at the highest point of this opening. The radical cure of a femoral hernia is rendered difficult because of the shortness of the femoral canal and the close proximity of the femoral vein, and because the canal is made up of dense tendinous structures. The stitches when applied create a great deal of tension. Cabot advises that a semicircular incision should be made through the fascia lata just beneath the saphenous opening, after the saphenous vein has been tied and cut away. The fascia can then be thoroughly separated, so that the lower wall of the femoral ring may be drawn upward, held with sutures without the least tension, and the whole canal tightly closed with ease.

NOW READY.

DIET LISTS
AND
SICK-ROOM DIETARY.

BY

JEROME B. THOMAS, M.D.,

Visiting Physician to the Home for Friendless Women and Children and to the Newsboys' Home; Assistant Visiting Physician to the Kings County Hospital; Assistant Bacteriologist Brooklyn Health Department.

ISSUED IN NEAT BOOK FORM, STRONGLY BOUND IN CLOTH, PRICE, $1.50.

Contains 160 detachable (perforated) Diet Lists for Albuminuria, Anæmia and Debility, Constipation, Diabetes, Diarrhœa, Dyspepsia, Fevers, Gout or Uric-acid Diathesis, Obesity, and Tuberculosis; also 40 detachable sheets of Sick-Room Dietary, containing full instructions for preparation of easily-digested food necessary for invalids. Each list is **numbered only**, the disease for which it is to be used in no case being mentioned,—an index key being reserved for the physician's private use.

Sent post-paid on receipt of price.

DIETS

FOR

INFANTS AND CHILDREN

IN

HEALTH AND IN DISEASE.

BY

LOUIS STARR, M. D.,

Editor of "An American Text-Book of the Diseases of Children."

230 Blanks (pocket-book size), perforated and neatly bound in flexible Morocco.

PRICE, $1.25 net.

The first series of blanks are prepared for the first seven months of infant life. Each blank indicates the *ingredients*, but not the *quantities*, of the food, the latter directions being left for the physician. After the seventh month, modifications being less necessary, the diet-lists are printed in full. Formulæ for the preparation of diluents and foods are appended.

Sent post-paid on receipt of price.

925 Walnut Street, Philadelphia, Pa.

"The work on the whole will commend itself highly to the practitioner."—*Archives of Pediatrics.*

APPENDICITIS.

Deaver[1] in **"Some Salient Points in the Diagnosis, Pathology, and Treatment of Appendicitis"** maintains emphatically that **early operation** is the only justifiable procedure and the only method of obtaining a certain way to recovery. He has operated upon 200 cases with only 2 deaths, and these in the first 100. He says there are 3 symptoms which cannot be mistaken: sudden onset of acute pain in the abdomen, which may or may not be accompanied by vomiting; rigid muscles on the right side of the abdominal wall; and tenderness in the appendix-region. Typhoid fever should not be mistaken for appendicitis. The former has a slow onset, no abdominal rigidity; if there is any abdominal tenderness, it is where the spleen is enlarged; the patient is very weak. There are headache, nosebleed, and characteristic temperature, whereas in appendicitis the surgeon feels a tender mass by rectal examination. Appendicitis could never be confounded with pelvic suppuration if early operation were always carried out. Abscess of the ovary and pyosalpinx are always associated with a record of an antecedent vaginal infection, and we find in Douglas' culdesac a mass of inflammatory material which is attached to the uterus, and which anchors this organ more or less firmly, and which may be distinctly outlined by vaginal or combined vaginal and rectal examination. In pus-affections of the kidney or ureter we do not find the cardinal signs of appendicitis which have been mentioned. An appendicitis-pain is occasionally referred to the left side of the abdomen, and in these cases it is extremely important to find out if there is an abscess in this region, and we find out by means of a rectal or vaginal examination. Deaver believes in removing the appendix even in pus cases. [The next article ably discusses the propriety of always removing the appendix.]

White[2] inquires if **the appendix should be removed in every case of appendicular abscess.** He tells us that the true mortality of early operation in cases in which appendicitis is present, as distinguished from cases in which it is only **diagnosticated;** the true mortality of the operation of removing the chronically diseased appendix in the interval between attacks, as distinguished from the mortality of removal of a normal appendix; the percentage of ventral hernias, peritoneal bands, and other sequelæ; the existence or non-existence of catarrhal appendicitis and of stercoral typhlitis; the alleged infective character of all appendicular inflammations; the proportion of second attacks after one mild attack, and the proportion of these which may be avoided by dietetic care; the value of appendix-bacteriology; endless minor differences as to the seat and character of the wound; the treatment of the same, etc.,—all these are problems not only awaiting solution, but questions many of which have two sides worthy of respectful consideration, and a final conclusion satisfying in every respect is to-day logically impossible. There are other points as to which White thought other surgeons were well agreed. He believed that few would dissent from the following rules: Immediate ope-

[1] Med. News, Dec. 21, 1895.

[2] Univ. Med. Mag., Mar., 1896.

ration when the onset of the case is marked by suddenness and severity, and whenever, even in a mild attack, the symptoms at the end of 48 hours are found unimproved or worse; whenever in cases seen later a firm, slow-forming, well-defined mass is felt in the right iliac fossa; whenever at any time there is a sudden increase in the acuteness of pain and a rapid diffusion of tenderness; whenever the appendix-infection is believed to be tubercular; whenever attacks of any type have been numerous or are increasing either in number or gravity, or have unfitted the patient for work or activity, or have caused local symptoms which are permanent or persistent or have at any time put the patient's life in great danger. Other questions there are to which the same assertion does not apply, and one of these has always been a source of grave anxiety to many operators. A short time ago White summarized his own view in regard to it by saying that it must be determined by future experience whether cases seen from the third to the sixth day, which present indications of a beginning circumscription of the disease by adhesions, and which tend to the formation of local abscess, will do better with immediate operation with the risk of infecting the peritoneal cavity, or with later operation when the abscess-wall is stronger and less likely to be broken through. This is the time which Richardson has described as "too late for an early operation and too early for a safe late operation;" and this distinguished surgeon has further stated that there is no more difficult operation in surgery than that of removing the appendix at this stage without infecting the general peritoneal cavity. White thought that his view in regard to this point was identical with that of every surgeon competent to pass upon it, and it was recently formulated as follows: "If there is a circumscribed abscess, it is poor surgery to insist in every case and at every period upon finding and attacking every appendix in the face of all obstacles. In many cases of circumscribed abscess, especially in those in which the appendix is bound down by adhesions in the depth of the wound, the surgeon should be content with evacuation, irrigation, drainage, and packing with iodoform gauze. Persistent search for the appendix and attempts at its removal in these cases are attended with such danger of opening the peritoneal cavity that they are not to be recommended."

Dr. White has seen a recent article in which statements are put forth diametrically opposed to these, and in which it is maintained that it is always advisable to remove the appendix in every case. This article led him to a serious consideration of the matter, with the result that his confidence in his original opinion was increased. The assumption that to leave an appendix which has sloughed or has been perforated or has been the seat of infectious inflammation, means the certainty of fecal fistula or of subsequent acute attacks, was positively contraindicated by his own experience and by that of the profession. He has operated and left the appendix in 37 cases of circumscribed abscess. In 2 of them a fecal fistula formed and closed spontaneously and permanently. In the third, still under treatment, it had become obliterated. The fact that White had no mortality in these cases justifies him in doubting the reliability of the other observer's sweeping assertions. These

assertions are further contradicted by current surgical literature, notably in the observations of Treves, Fowler, and Richardson. White asked for an expression of opinion from McBurney, Bull, Senn, Halsted, and Richardson. McBurney says that there are certainly some cases, and not a few, in which the appendix is so deeply imbedded in the wall of the abscess that to insist upon its removal would be to incur unjustifiable risks. Attempts at removal often mean great prolongation of the operation under unfavorable circumstances, and such danger of infecting fresh peritoneal surface that one had best be content to leave the appendix or its remnant to be disposed of by obliteration in wound-healing or by its removal at a more favorable time through a second operation. Bull does not believe that it is always advisable to make the operation a complete one. He searches for and removes the appendix when it can be readily found and separated from adhesions; and this is, as a rule, feasible in cases operated upon up to the 7th day. In cases operated on at a later date or those in which the abscess is rather large, distinctly circumscribed, and with firm walls, he does not attempt to remove the appendix. Senn regards a persistent search for the appendix in such cases as extremely hazardous, as it often results in fatal septic peritonitis. Halsted says that he does not remove the appendix in every case of appendicitis. If there is only one abscess, and it can be evacuated without entering the uninvolved part of the peritoneal cavity, he treats it simply by incision and drainage. Richardson supports White's position strongly, and believes that a man is better off living with an appendix at the bottom of an obliterated pus-cavity than dead with a beautiful specimen in a bottle on the surgeon's table. In conclusion White says that we should aim first at the recovery of the patient, and only secondarily at the performance of a theoretically complete operation. [We are in cordial agreement with Prof. White in all of his assertions upon that point. We believe, and most emphatically, that the rule of invariably removing the appendix is a bad one, and must inevitably cause some deaths which could be prevented. Dogmatic assertion may be an easy way for a surgeon to escape from difficult problems, but it is hard upon the patient, who must bear the brunt. Facts are stubborn things, and the most absolute dogmatism cannot lessen their force. White's view is cautious, scientific, and, we believe, correct.]

Meyer[1] says operation must be done at once in diffuse perforative appendicitis. In case of acute appendicitis the patient must be carefully observed, and a pulse which rises above 116 to 120 is an indication for operation. In cases of doubt we should operate. A case of mild appendicitis also, after the first severe attack from which the patient recovers without immediate operation, the appendix should be removed, as if left alone it will be likely subsequently to cause serious and even fatal trouble. In these interval-operations we may separate the abdominal muscles according to the direction of their fibers, and thus protect the patient from the danger of a ventral hernia. [The exact time for operation and the suitable case for operation cannot as yet be always determined with absolute certainty. Each case must be studied and treated upon

[1] N. Y. Med. Rec., Feb. 29, 1896.

its own indications. The question is of cases rather than of classes. Every conscientious surgeon must often be in doubt. Simply because it is easy to say operate on every case does not always make it right to do so.]

McGuire[1] as regards **relapsing appendicitis** cited 17 cases treated by operation, and strongly opposed any routine operation in an acute attack. He states that he is not always in a great hurry to operate, but is inclined to wait for the more acute symptoms to wear off, and to operate, if at all, after suppuration has taken place or in the interval between attacks. Cabot[2] maintains the necessity of removing the appendix in relapsing appendicitis. He states that the operation done between attacks, when the tissues are comparatively healthy and not already filled with microorganisms, is free from many of the dangers which surround an acute attack, and its mortality is comparatively trifling. Bull's statistics put the mortality at about 3%. His personal experience comprises 32 operations, without a death. Murphy[3] has operated upon 207 cases of appendicitis with a mortality of a little less than 10%, and he operates on every case that comes under his notice, and strongly maintains the necessity of such a procedure. [Greig Smith, in discussing the question of operation when mild appendicitis exists, says: "It is impossible to be definite and wrong to be dogmatic"—a comment which we will insert in this place.]

Page[4] presented the records of some cases illustrating the diseases in the **surgery of the vermiform appendix.** One was an acute abscess from perforation in which he drained the abscess; one was an acute suppuration from perforation with symptoms simulating general peritonitis, in which recovery was obtained; the third was a very remarkable case in which an acute abscess arose from a perforated appendix, with symptoms suggestive of a perforative ulcer of the stomach. A median celiotomy was done, nothing was found, and the patient died. One was a case of operation for recurrent attacks of appendicular colic with recovery, and a fifth case was of the same description. Page, speaking of Case 3, says that it was one of the most deplorable cases he ever had to deal with. The diagnosis of perforation of the stomach having been made, it would have been difficult for any surgeon not to act upon it, especially as the tympanitic distention seemed to point to air in the perineal cavity. He says had he followed his own rule, unfettered by any previous diagnosis, he is satisfied that the iliac resistance would have led him to open the abdomen, and he now regrets that he did not explore this region as soon as the opening in the middle had failed to discover the cause of the supposed symptoms. The case powerfully illustrates the manner in which a local, acute, and circumscribed abscess from appendix-perforation may simulate a general peritonitis from an entirely different cause. The appendix should never be forgotten in all cases of the kind.

Morris[5] reports a series of 100 consecutive operations for appendicitis. All of the acute-abscess cases were operated upon at once, with the exception of 2,

[1] Med. News, Nov. 23, 1895.
[2] Boston M. and S. Jour., Dec. 26, 1895.
[3] Jour. Am. Med. Assoc., Mar. 30, 1896.
[4] Lancet, Mar. 7, 1896.
[5] Am. Med.-Surg. Bull., Feb. 22, 1896.

who died before he arrived at their homes. Of the 38 abscess-cases, 36 recovered and 2 died; 1 died from suppurative nephritis, the other from septic peritonitis. The appendices were removed in all but 5 of the acute cases. He advocates a very small incision. In the cases of appendicitis after a small incision he cleans abscess-cavities with hydrogen dioxid and normal salt-solution, drains with a capillary wick, and separately sutures the abdominal layers. He opposes the use of gauze-packing for drainage, and disapproves of counter-openings. He does not use opium after operations. The reason he has no ventral hernias is because he sutures the abdominal walls accurately, and in suitable cases also sutures the cecum and the margins of the abdominal wound. In cases of acute and chronic appendicitis without abscess he operates through a $1\frac{1}{2}$ in. incision. His results are shown in the appended table:

Classification of Cases.

"Acute appendicitis, with abscess	34
Chronic appendicitis, with chronic abscess	4
Acute appendicitis, without abscess	12
Chronic appendicitis, without abscess	40
Tuberculosis of appendix	6
Cancer of appendix	1
Appendix obstructed by torsion	2
Uninfected appendix, with concretion	1
Total	100
Deaths	2
Post-operative hernia	0
Males	76
Females	24"

[The small incision in many cases we believe to be unsafe, for the surgeon who operates through a very small incision is liable to seriously injure the viscera. Morris does not make counteropenings, but in cases of general septic peritonitis thorough cleansing is impossible unless a counteropening is made. The fact that iodoform-gauze does not drain pus well is undoubted, and we question if the capillary drain will do so any better.]

Morris[1] presents another article called forth by criticisms on his statistics and methods. He calls this article "Committing Taxidermy upon Appendicitis Patients." He states that gauze-packing in the peritoneal cavity depresses the patient, often keeps him in a condition of shock, obstructs the bowel, stimulates the peritoneum to throw out great quantities of decomposable lymph, and irritates the bladder and ureter. If iodoform-gauze is used, iodoform-poisoning will often supervene, coming on sometimes insidiously and being frequently unrecognized, the surgeon merely noting that the patient's pulse is rapid and weak. [An iodoform-gauze which does not cause poisoning is spoken of on p. 206.] The removal of the gauze occasions great pain, and the large opening maintained by the gauze frequently becomes the seat of ventral hernia. There is another thing that gauze-packing does not do, and that

[1] Am. Med.-Surg. Bull., May 9, 1896.

is drain. The lymph fills its meshes and coagulates and prevents drainage. Morris opposes large incisions, advocates the use of hydrogen dioxid and saline solutions, and strongly maintains the value of early operation. He differentiates catarrhal colitis with involvement of the appendix from infective appendicitis. He does not operate upon the former class of cases, but operates upon nearly every case of real infective appendicitis, no matter what stage it presents. He tells us that by these methods of treatment we can reduce the death-rate of infective appendicitis to a fraction of 1%. Nevertheless, medical treatment is still employed with its death-rate of 10% in attacks and 30% in cases. [Iodoform-gauze is not entirely satisfactory, but we would fear to do without it in many cases, especially when it is desirable to circumscribe an infected area from the peritoneal cavity.]

Allis[1] advocates in certain cases **drainage through the rectum** in pelvic abscess due to appendicitis. He cites 3 cases, and says that he first hesitated to drain into the rectum, fearing that a permanent fistula would result from the passage of fecal matter from the bowel into the abscess-cavity, but all 3 of his cases did well, and healed earlier than many did when drained at the least dependent point.

Robinson[2] made a study of the appendix and cecum in 128 adult post-mortems. The bodies were taken just as they came, consecutively, absolutely without selection. The examinations were conducted by first examining the condition and position of the great omentum and its relation to the ceco-appendicular apparatus; the appendix was carefully observed as regards its longitudinal position and pathologic condition; the cecum was noted in relation to its anatomy and pathology. He assumed as the standard of reference for the ceco-appendicular apparatus the psoas and iliac muscles; 72% of peritonitis occurs in adults around the ceco-appendicular apparatus; hence he terms this region the major region of peritonitis, the other three major regions being the pelvis, gall-bladder, and mesosigmoid. It seems to Robinson very evident that the factor which induces 72% of peritoneum-adhesions around the ceco-appendicular apparatus is the psoas muscle, and that the frequency of appendicitis in men over women may be looked for in the activity of the psoas muscle on the appendix. The appendix in men is more frequently in contact with the psoas muscle than in women, and in the relation of the motion of the psoas muscle and the condition of the appendicular contents the position of the wall are etiologic factors in appendicitis.

DISEASES OF THE INTESTINES.

Thompson[3] reports 2 cases in which **perforation of the intestine** resulted from typhoid fever. In neither of these cases was the diagnosis of typhoid fever suspected. The first patient was a walking-case who was suddenly seized with severe abdominal pain and vomiting. Four days later there was enormous distention of the abdomen, with pain, hiccough, and vomiting.

[1] Ann. of Surg., Mar., 1896.

[2] Med. Rec., Nov. 30, 1895.

[3] Med. Chron., Sept., 1895.

Celiotomy was performed, and a large amount of partly purulent fluid ran out, and near the cecum a large collection of fluid was found, which fluid was feculent and contained masses of lymph. The great distention of the intestines prevented a thorough examination of the abdomen. One of the distended coils was punctured with a large trocar and cannula, and about 2 quarts of fecal matter removed. The opening was immediately closed. In conducting the examination of the intestines a perforation of the ileum was found about 12 inches from the ileocecal valve. The perforation was oval, $\frac{1}{4}$ in. long and $\frac{1}{8}$ in. wide; the edges were clean cut, grayish, and surrounded by a zone of intense inflammation. This opening was closed with 3 interrupted sutures passed through the edges of the ulcer, and the serous coat brought together by a continuous silk suture. The abdominal cavity was irrigated and a drainage-tube was inserted. The patient died in a few hours. Autopsy proved the existence of typhoid fever. The second patient had been feeling ill for a couple of weeks. There were distention of the abdomen and a weak and rapid pulse. Opening the abdomen permitted the escape of gas and fluid. Thompson found a perforation in the cecum. The gut was so disorganized that an artificial anus was made. The patient died in 8 hours, and the autopsy proved the existence of typhoid fever. [Most perforations occur in the ileum, but they may take place in the colon or cecum. Abbé has shown that excision of a portion of the bowel is rarely necessary, inversion of the ulcerated area being all that is necessary (see *Year-Book*, 1896). A median incision is certainly best, and drainage is advisable.]

Wiggin[1] in an article dealing with the **operative treatment of perforation in enteric fever** tells us that Dr. Bontecou of Troy was the first person in the United States to operate for this form of perforation, and that this surgeon had claimed that when such a mortal accident happens celiotomy cannot impair the patient's chances, and may improve them. Dr. Van Hook reported the first successful case, and said: "It is strange that a question involving the only promise of help for $5\frac{7}{10}\%$ of all those dying of typhoid fever should not have excited even more interest and discussion." Dr. Abbe in the report of a recent successful case said: "Why one class of cases should be left to die, while we operate on all appendicitis cases when perforation can be recognized, does not appear." Prof. Kussmaul of Strasburg said: "Granted that the chance of a successful issue is heavily against you, that the patient is in the midst or at the end of a long sickness, that his tissues are in the worst state to stand the injuries of the surgeon's knife, that the lesions of the gut may be extensive, that the vital forces are at the lowest ebb, operation should be done. No one yet has hesitated to perform tracheotomy in the laryngeal complications of enteric fever which required it to save life, for these reasons." Wiggin says there are 24 cases on record with 6 recovered. If those cases are rejected in which the diagnosis is somewhat doubtful, there are 17 patients with 3 recoveries. The first recovery was obtained by Van Hook, the second by Netschajaus of St. Petersburg, the third by Dr. Abbe of New York. The

[1] Med. Press, Jan. 1, 1896.

writer's opinion is that when the physician takes charge of a case of enteric fever he should prepare himself to act with promptitude upon the occurrence of perforation. It is well to remember that while there should be the least delay possible, these patients rarely die in the first stages of collapse, and that this condition is not favorable for operation. As soon as the diagnosis of perforation is made the patient should be stimulated by strychnin and morphin. If he rallies, the operation should be performed without loss of time. If the patient does not rally, operation would be useless. Dr. Abbe has said that he considers it essential that the surgeon should never be so hasty in getting at his work that he enters upon it handicapped by poor assistants, poor light, or poor arrangements for irrigation. The arrangements for the operation should be made while the patient is being stimulated. Patients of this class do not bear anesthesia well. The writer prefers to use a closed inhaler of the Clover type or Dawbarn's modification.

[Dr. James C. Wilson was the first person to recommend operation in these cases (see Phil. Med. Times, Dec. 11, 1886). Morton, according to Greig Smith, recorded 2 operations in 1886. In the vast majority of cases operation holds out no hope, and it is unquestionable that occasionally recovery follows perforation when no operation is done. Prof. DaCosta used to speak in his lectures of such a case. We believe that operation is justifiable when the perforation is undoubted and when the patient reacts from the first depression. If he does not react, we must not operate. Even under the most favorable circumstances operation holds out a very slender hope, but it is our duty in most cases to grasp at this hope; and this is especially true in walking cases. The danger of the operation is made evident by the statement of Greig Smith, that out of 25 operations only 1 person recovered. The same distinguished surgeon says that of these 25 cases only 1 was certainly typhoid. Van Hook's article upon this subject is extremely valuable. (See Med. News, Nov. 21, 1891.)]

Hotchkiss[1] reports a case in which perforation occurred on the 15th day of typhoid fever. Operation was performed and the patient died in $4\frac{1}{2}$ hours after the operation. In spite of this fatal result, Hotchkiss believes that our only hope lies in an early operation. In the case reported 10 or 12 hours had elapsed since the perforation had occurred, and a general septic peritonitis had already intervened. He thinks the operation should be classed with tracheotomy for laryngeal stenosis, and with herniotomy for the relief of strangulation, as an occasional life-saving procedure.

Warren[2] describes a case of perforating ulcer of the duodenum. [In these cases a diagnosis is very rarely made before operation. Percy Dean in 1894 performed the first successful operation. Smith advises incision over the seat of perforation; that is, if the condition is suspected. If we follow this rule, the incision will be above the umbilicus and through the right rectus muscle. The ulcer is usually in the first part, but may be in either of the other two portions. In order to expose the lesser omental cavity we must split the

[1] N. Y. Med. Jour., Jan. 11, 1896. [2] Boston M. and S. Jour., May 6, 1896.

gastrocolic omentum in part. The ulcer is simply inverted, excision being unnecessary. Drainage is required. (See *Year-Book* for 1896.)

Herbert W. Allingham[1] advises the use of **a new bobbin** for intestinal anastomosis which he thinks obviates disadvantages, notably in most of the other mechanical devices (Fig. 42). He maintains that some form of apparatus is necessary to unite hollow viscera to one another. The bobbin acts as a kind of splint while union is taking place, preventing any contraction or dilatation of the gut at the seat of union, and thus doing away with any chance of leaking. When no bobbin has been used the seat of suture has no support, and a very slight dilatation or contraction of the gut may allow some leakage. Again, rest and fixation favor union. He thinks that the bobbin of Mr. Mayo Robson is objectionable, because the flanges at the ends of the bobbin are separated from one another by about $\frac{3}{4}$ in.; hence when viscera are brought together it is necessary to use some kind of suture running from one to the other, a process which takes time. Moreover, when the viscera have been brought together over a bobbin they can slide from one end of it to the other. Senn's plates allow the ends of the incision in the viscus to fall together, and thus the communications between the viscera become too small later, because there is nothing to keep the openings patent while union is taking place. There are several objections to Murphy's button. The button may be delayed in the intestine for a very long time, as in Lane's case, in which it did not come away even in 160 days. The button might be unable to pass the ileocecal valve, and might cause obstruction at that point. In gastroenterostomy the button might fall back into the stomach, and then be unable to pass the pylorus or be vomited from the esophagus. It is not judicious to press intestines together at their seat of union by a button which can come away only by absorption or by sloughing of the pressed parts. No less than 5 cases have come to his knowledge in which sloughing with perforation took place at the seat of union, the patients dying from a consequent peritonitis. It is desirable that the intestines at the seat of union should be held together by pressure, but this pressure must not be too great or too small. It should not be sufficiently great to necessitate any absorption or sloughing in order to free the button. He believes that his bobbin remedies the above-mentioned disadvantages. The bobbin is of bone or ivory, and it consists of two cones with their apices coming together to form the center. They are carefully decalcified to within about $\frac{3}{16}$ cm., leaving at the junction of the two cones a hard, unyielding portion upon which any pressure from the suture is borne. The ends of the tubes are quite soft. There are several sizes. This bobbin keeps the parts at absolute rest, can be absorbed, and can be liberated without any absorption or sloughing of the parts it unites, and because of its shape it cannot slip away until the decalcified bone is absorbed. When the sutures in each piece of intestine are tied,

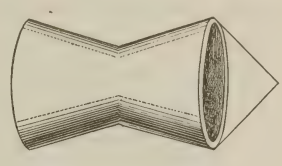

FIG. 42.—Allingham's bobbin (Lancet, Aug. 31, 1895).

[1] Lancet, Aug. 31, 1895.

the parts to be joined are with certainty brought together, and yet no excessive pressure is exerted upon the edges. The illustrations (Figs. 42–45) exhibit his bobbin and its use. Though the bobbin may be employed to unite intestines to stomach, gall-bladder to intestine, and indeed in any form of anastomosis, its use is most conveniently explained by presuming that two pieces of intestine are to be united end to end. Into or around each piece of intestine a continuous silk suture is passed, which includes in each stitch the peritoneum, the muscular coat, and the mucous coat (Fig. 43). One end of the bobbin is inserted into one piece, and the suture is pulled tight by a knot twice threaded, so that it will not slip out; the final tie is not made until the other end of the bobbin has been inserted into the other piece of bowel (Fig. 44). After this one of

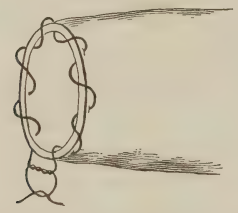

FIG. 43.—Use of the bobbin, first step (Allingham, in Lancet, Aug. 31, 1895).

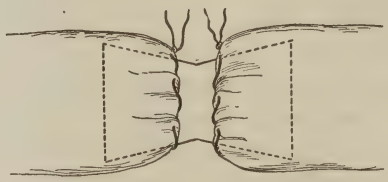

FIG. 44.—Second step (Allingham, in Lancet, Aug. 31, 1895).

the sutures is tightened up to its utmost. This brings the part down to the center of the bobbin. As the bobbin consists of two cones with their apices pointing to its center, the tighter the suture is drawn the more completely must it draw the intestine to the apex of the cone. Thus the parts are brought into exact apposition and are pressed together (Fig. 45), and a few Lembert sutures are inserted at various points, or a continuous Lembert suture may be used all around. It is wise to scarify the intestinal peritoneum for about $\frac{1}{2}$ in. around the seat of union, for this scarifying promotes the exudation of lymph. He has only had one opportunity of using this bobbin upon the living subject, and in this case it gave excellent results. [Many surgeons reject mechanical aids to operation, notably Abbe of New York. The question is still doubtful, and the future must solve the problem.]

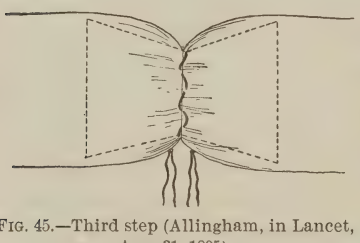

FIG. 45.—Third step (Allingham, in Lancet, Aug. 31, 1895).

Chaput[1] describes **a new button** for resection and anastomosis in intestinal operations. The annexed cuts (Figs. 46–53) display its shape and the mode of its application.

Another form of bobbin is described by P. J. Hayes[2] of Dublin. It is made of bone or ivory; the central part has been longitudinally segmented by means of a fine saw, and the ends of the bobbin up to a little beyond the extremities of the skin-lines are decalcified. (See Figs. 54–57.) Still another

form of bobbin for intestinal anastomosis is suggested by J. Jackson Clark [1] of London. In this the pressure is made by india-rubber rings, the edges of which are rounded off (see Figs. 58, 59).

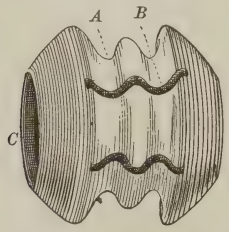

FIG. 54.—Double bobbin, shaded ends decalcified: *A*, unshaded central ridge and grooves, not decalcified; *B*, saw-lines are seen segmenting the undecalcified bone and extending a little way into the decalcified parts; *C*, lumen of bobbin (Hayes, in Lancet, Dec. 28, 1895).

of any special apparatus. He turns back the peritoneal layer from one end of the small intestine after resecting a portion of the gut, suturing the muscular coat thus exposed to the peritoneal coat of the other end of the intestine, subsequently turning down the reflected peritoneum over the first row of sutures, which are thus completely buried, and suturing its deep fibrous sur-

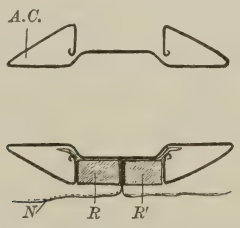

FIG. 58.—Longitudinal section of the bobbin, the intestine, *N*, and india-rubber rings (*R* and *R'*) shown in section below (Clark, in Lancet, May 9, 1896).

face to the outer serous surface of the unreflected portion of the intestine. He founds this operation on the suggestion of Greig Smith that serofibrous union

is more valuable than the union of peritoneum to peritoneum. (See *Year-Book*, 1896.) This serofibrous union unites quickly and firmly. The inner sutures are passed through the muscular coat only of one end of the bowel, whilst the outer sutures unite the peritoneal coats only. The accompanying diagrams exhibit the method of employing this suture (Fig. 60). The inner

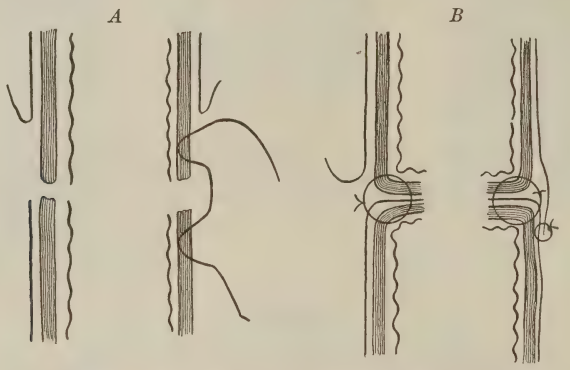

FIG. 60.—Suture employed in rapid enterectomy (Rogers, in Brit. Med. Jour., Apr. 11, 1896).

wavy lines represent the mucous membrane, the thick lines the muscular coat, and the thin straight lines the peritoneal coat. Figure 60, *A*, represents on the left-hand side the peritoneal coat turned back from one end of the bowel, and on the right side shows the method of passing the inner suture. Figure 60, *B*, shows on the left side the parts brought into apposition before tightening the inner suture, and on the right side the second suture in position, completing the junction. This mode of operating is said by Rogers to offer certain advantages. It can be inserted without the aid of special appliances. It can be completed in half an hour, or a little longer than the time required with the aid of special appliances, such as plates, buttons, and bobbins. The junction is a double serofibrous one, which Greig Smith has shown gives the maximum of rapidity and firmness. The mesenteric site can be made very firm by the apposition of the muscular coat of one end with the peritoneum of the other and the subsequent covering up of this suture by the reflected peritoneum. When special appliances are at hand they will probably be preferred to this method, but in emergency cases Rogers thinks it is a valuable plan. He thinks it quicker and more efficient than suturing with interrupted Lembert sutures, in which proceeding both Jacobson and Treves agree from 25 to 40 sutures are required, and even then the mesenteric junction gives cause for anxiety.

The Medical News (Nov. 16, 1895) contains a report of 111 additional cases operated on with an **anastomosis button** by Murphy. The London Practitioner of Feb., 1896, has given an excellent resume of the salient points of this article. The report includes 61 cases of gastroenterostomy for malignant disease, with 28 deaths. The 34 cases which have been added since the last report show a mortality of 7. Death is in most instances due to shock or exhaustion, proving that the operation should not be practised on people who

are in a very weak and emaciated condition, and on such people it cannot be expected to materially prolong their lives or modify their sufferings. In some cases the poor result of the operation was due to the employment of too small a button. In other cases the button slipped back into the stomach. Murphy tells us this unfortunate complication can be obviated by the use of special oblong buttons. He thinks that the posterior wall of the stomach is the proper situation to make our anastomosis. He never applies supporting sutures around the button, except in cases where they are necessary to relieve tension. He advocates scarifying the peritoneum of the stomach to hasten union; 7 cases of pylorectomy are recorded, of which 2 died; 1 case died of exhaustion, and the other died from peritonitis the result of leakage. Pylorectomy is only suited to recent cases of malignant disease; 51 cases of choleduodenostomy are reported, with 2 deaths: 1 death was from septic peritonitis, the infection having taken place during the operation; the other was from hepatic hemorrhage occurring in ruptured adhesions. This operation is employed when the cystic duct is permanently obstructed, when the common bile-duct is obstructed, when prolonged drainage is necessary in septic cholecystitis, and in cases of fistula of the gall-bladder where the continued loss of bile is responsible for advancing emaciation. He has altered his view in regard to the removal of calculi at the time of operation. He used to advise against it, but now recommends it. He says we should not undertake any very long operation in patients who have been jaundiced for a considerable time, because such patients are very prone to shock and to uremia. In considering the statistics of intestinal approximation the pathologic conditions which made the operation necessary must also be borne in mind, as the dangers of such lesions are often so extremely great as to make any operative proceeding whatever very risky. He reports 34 resections for gangrene with 8 deaths; 15 cases of intestinal approximation for fecal fistula with 3 deaths; 53 cases for nonmalignant obstruction with 6 deaths; 41 cases for malignant obstruction with 15 deaths.

In discussing the question of resection for intestinal perforation, either traumatic or pathologic, he tells us that the danger which accompanies such a condition is always extremely great, and quotes Leube, who from a study of 322 cases showed that if operation were performed within 12 hours of the injury, there was a mortality of 58.2%, while if the operation was performed at a later period the mortality was 79.5%. In bullet-wounds of the abdomen Murphy never eviscerates. He examines the entire intestinal tract, it is true, but never exposes more than 12 in. at a time. Each perforation as it is found is clamped with hemostatic forceps, but the whole extent of the injury must be definitely known before any operative measure is undertaken. The perforations made by a single bullet number from 1 to 18, and they are usually in adjacent areas if the small intestine is involved. We often find one or several openings in the small intestine, and in the same cases one or two openings in the large bowel. The median incision is the one he advises, and he says that it is often possible to remove in one piece the entire damaged section of

bowel. In some cases two or more buttons may be employed; 3 or 4 cases of the employment of the buttons for such intestinal resection have been placed on record. All the patients made an operative recovery.

Murphy considers the various objections which have been urged against the buttons. He maintains that since there is no tendency to contract, and the size of the opening is not too small, a No. 3 button is quite large enough for operations upon the small intestine, and a No. 4 button is only required in operations upon the large intestine. He does not think that the button can ever cause obstruction unless there is some preexisting stenosis. All its possible dangers are more than compensated for by the ease and certainty with which it can be applied. Another objection that has been made is that the lumen of the button itself may become blocked—3 such cases have been recorded—but Murphy says that if the surgeon keeps the patient's bowels in a loose condition after the operation, such blockage cannot occur. Murphy maintains that the greatest possible care must always be taken to see that there is not a ligation of too many mesenteric vessels. If too many of these vessels are ligated, sloughing and perforation are almost certain to follow. [Murphy's button enables the surgeon to lessen the time of operation. Many surgeons fear it will produce gangrene, and will not use it. Other surgeons condemn it because they have not used it properly. Others still will not employ it because they fear it will block or will not pass or make too small an opening. Murphy disposes of most of these objections. The opening is small, but then it does not, as a rule, tend to contract. The button does not fail to pass unless a constriction exists lower down, and this ought to have been found during the operation. When it does not appear in the stools a finger inserted into the rectum may discover it. In gastroenterostomy there is some danger of retention, but this may be prevented by using an oblong button. Blocking will not take place if the feces are kept liquid by salines. It is not necessary to surround the line of serous junction with inversion sutures; they do more harm than good, and take time to insert. The button is a time-saver, and in abdominal operations saving time is often saving life.]

Kidd[1] reports 3 remarkable cases in which **intestinal obstruction** was due to fecal accumulation **associated with displaced kidney.** In each of these cases there was a long history of constipation. The symptoms of obstruction were pronounced. Distinct swelling was manifested in the hypochondriac and iliac regions. The signs of obstruction passed away under the influence of opiates, fomentations, starvation, and enema. As the obstruction passed away in each case the tender mass diminished in size and was made out as a displaced kidney. Kidd previously described 4 cases of a similar sort. All of these 7 cases were women. The fecal accumulation in this case was in the right half of the colon, and the reason of the obstruction was purely mechanic. A very slight degree of pressure on the lumen of the large intestine suffices to partially arrest the upward passage of its contents. As the nerve-supply of the right half of the colon and that of the suprarenal body

[1] Lancet, Dec. 21, 1895.

and kidney is derived from the outer side of the solar plexus, and as the nerves of the suprarenal body are large and directed horizontally outward, it is quite reasonable to suppose that a displaced kidney may interfere with the nerves of the organ in a way which may communicate itself to another organ whose nerves arise from a neighboring part of the great plexus; hence the obstruction may be partially mechanic and partially nervous. The fact that many displaced kidneys give rise to no symptoms does not disprove this suggestion as to the connection between the renal and suprarenal plexuses and the superior mesenteric plexus, for many displaced kidneys are tender and somewhat enlarged for a short time only, and influence through the nerve-relation only takes place during periods of tenderness and enlargement. Patients with displaced kidneys should be instructed to attend to the action of the bowels as long as they live.

Winter[1] presents 3 cases of **intestinal obstruction** which he thinks were due to **occupation.** The patients were cork-cutters, and the severity of the symptoms was in direct proportion to the length of time they had been in the employment. The cases occurred in one house, and a careful investigation proved that they were not due to any errors in diet. In pursuing their occupation cork-cutters assume a bent position of the body, which probably constricts the gut sufficiently to cause obstruction. Each case gave a history of chronic constipation which began a few weeks after engaging in that occupation. The mere fact that the occupation was sedentary fails to account for the condition, as the patients were young and healthy men and accustomed to take much physical exercise out of working hours. Winter thinks that a person engaged in any employment in which a similar position is assumed is liable to an attack of intestinal obstruction, and holds that in such an event the physician should make a thorough examination into the condition of the sigmoid flexure. Each of these patients recovered.

Legeue[2] discusses the subject of **postoperative intestinal obstruction.** He states that intestinal obstruction after abdominal operation is not infrequent. Spencer Wells and Fritsch estimate that 1% of cases after ovariotomy develop obstruction. [Greig Smith says 2% of all deaths after celiotomy are due to it.] Legeue has collected 57 cases, 27 of which followed ovariotomy; 9 followed removal of the appendages, and 4 abdominal hysterectomy; 9 followed vaginal hysterectomy; and 8 followed operations for hernia. In some cases the symptoms arose within 10 or 15 days of the operation; in others, within 3 or 4; in others, again, they did not arise for months or years. Many pathologic conditions may be causative of such obstruction: 1. Obstruction may result from some obstacle arising at the seat of operation. The commonest obstacle is adhesion between the coil of intestine and the raw surface, the raw surface being possibly the edges of the abdominal wound or the pedicle of a tumor or the stump of a divided portion of omentum, or the opening at the top of the vagina which is left by a vaginal hysterectomy. Such an obstacle may be due to the use of gauze in plugging the cavity or to

[1] Am. Med. Surg. Bull., Mar. 21, 1896.

[2] Gaz. des Hôp., Nov. 23, 1895.

the use of pedicle-forceps applied behind the pedicle of the tumor. The adhesions which arise from such maneuvers may not be the primal cause of the obstruction, but may lead to other conditions which cause obstruction, such as a volvulus or a twist in the gut. Anchoring the pedicle of the ovary or the uterus in the abdominal incision may give rise to obstruction, and operations for intestinal anastomosis may also induce it. Some cases have been due to plugging of the vagina too firmly for hysterectomy, thereby blocking the rectum by pressure. Some few instances are due to paralysis of the gut. 2. Obstruction may result from some obstacle independent of the focus of operation, although such obstruction is far rarer than that which we have just discussed. Legeue mentions 3 cases, in all of which the site of the obstruction was the splenic flexure of the colon, the transverse colon having been displaced as the result of the operation. In 1 case obstruction came on 3 days after operation; 5 days after operation celiotomy was performed, and a band was found reaching from the spleen to the transverse mesocolon, which caused flattening out of the splenic flexure. The patient died, and postmortem examination showed that as long as the transverse colon was kept in the position it must have held before the removal of the cyst by the first operation there was no obstruction, but as soon as the cyst was removed it was allowed to fall downward and obstruction must have occurred. In another case which occurred in the practice of Laroyenne of Lyons there was no band, but the splenic flexure fell down in the same manner. Legeue maintains that the splenic flexure is naturally kept in position by a peritoneal reflection shaped like a fan, which he calls the left colic ligament. When the abdomen is filled by a large ovarian cyst the transverse colon is pushed up, and this ligament becomes secondarily shortened. As soon as the cyst is removed the colon falls into its normal place, the shortened ligament makes traction, and obstruction follows. In the third case obstruction arose in the splenic flexure of the colon because of traction exerted by the removal of a very large piece of omentum during the radical cure of hernia. 3. Obstruction arising apart from any mechanical obstacle. Under this distinction the author includes those disputed cases in which obstruction arises from paralysis of a very small segment of the bowel. Such cases are very common after strangulation, not unusually cause death, and yet after death the postmortem discloses no cause for the condition. Legeue believes that such cases do exist, and are not always due to acute septic poisoning or to obstruction which ceased after death. The author discusses the prevention of adhesions in abdominal operations. He tells us that it is impossible to remedy the raw surfaces which remain after dividing adhesions, though we should as far as possible cover these raw surfaces with serous membrane if the attempt does not involve the expenditure of too much time. Apart from such states, there are two great causes of adhesions—the irritation caused by antiseptic agents and by exposing the parts to the air. Normal salt-solution is the only fluid which should be applied to the contents of the abdomen. The experiments of Walthard have proved that if the intestines are exposed to the air for more than 20 minutes, endothelial desquama-

tions take place and adhesions are bound to form. The great preventive of this condition is wrapping the parts in gauze wrung out of normal warm salt-solution. The author then discusses the diagnosis of these conditions. He tells us that the suppression of flatus is complete in obstruction, is never complete in peritonitis, is very rarely complete in intestinal paralysis. Vomiting if due to chloroform usually ceases soon, but if vomiting persists for several days or if it begins again after once stopping, the suspicions of the surgeon should be excited, and he should never wait to operate until the vomiting becomes fecal. Temperature, as a rule, is low in obstruction and elevated in peritonitis, but this is not always the case. Pain is great in peritonitis, and there is rarely much abdominal tenderness in the early period of obstruction. There is no characteristic sign of obstruction, but the combination of phenomena is tolerably positive. These combination-phenomena are the failure to pass flatus and feces, the existence of persistent vomiting without marked elevation of temperature, and the painless distention of the abdomen persisting after the administration of purgatives or enemata. The treatment he advises is the administration of a purgative followed by the use of enemata. If these means fail to relieve the symptoms, open the abdomen, find the obstruction, and treat it according to the general rules of surgery. He believes in dealing directly with the obstruction rather than making an artificial anus. [Open the abdomen through the old incision.]

Sweetnam [1] maintains that **tympanites** may be relieved by posture. In very extreme distention the knee-chest position is advisable, but in cases of moderate distention we may place the patient upon the side and elevate the foot of the bed. This treatment is applicable not only to distention which follows abdominal operations, but it might be applied with advantage to typhoid fever. It seems to do no good in subjective cases of general peritonitis. He was led to try this plan of treatment because while watching Kelly of Baltimore making a rectal examination, the patient being in the knee-chest position, he was able to see the rectum straighten out, the additional length being contributed by the unfolding of Houston's creases. These folds absolutely disappeared. It may be necessary to keep the hips in the elevated position for 10 or 15 minutes before the contents of the abdominal cavity gravitate sufficiently from the pelvis to enable the upper portion of the rectum to pass out of the pelvis toward the abdominal cavity. Relief will not be secured until this occurs. In marked tympanites the distention is practically confined to the large intestine, and obstruction to the escape of flatus is due to the downward pressure of the descending colon and sigmoid flexure upon the upper portion of the rectum, forcing the folds of Houston one upon the other and bringing about for the time being an impermeable stricture. An attempt to pass this by the soft-rubber tube will fail, because the tube will coil upon itself. By inverting or partially inverting the patient we remove through the aid of gravitation the pressure from above and thus liberate the imprisoned gas. [In tympanites following

[1] Ann. of Surg., Mar., 1896.

celiotomy we would not be willing to depend upon posture alone, but would also pass a rectal tube and purge the patient.]

Beck[1] writes an interesting and instructive article upon **Subphrenic Abscess,** reporting 5 successful cases of his own, and presents a study of the topography, pathologic anatomy, diagnosis, prognosis, varieties, course, and therapy. The treatment must be surgical. Evacuation can only be effected by a wide opening, and this opening is secured by resecting a piece of the rib. [Maydl in a well-known monograph makes 12 groups of subphrenic abscesses: 1. Stomachal; 2. Intestinal; 3. Perityphlitic; 4. Due to echinococci; 5. Due to trauma with unbroken skin; 6. Cholangitic; 7. Perinephric; 8. Metastatic; 9. Due to wounds of the subphrenic space; 10. Costal; 11. Thoracic; 12. Various (as fat-necrosis from pancreatic disease). Abscesses are further divided into extraperitoneal and intraperitoneal, the former most likely to break into the pleural sac. Spontaneous cure may occur from rupture into the lungs or a hollow viscus, but the surgeon must seek cure by operation and not hope to gain it by luck. Maydl shows that out of 104 cases not operated upon only 6 recovered, while out of 18 cases operated upon only 11% died. Most of these cases, Lampe shows, take origin from the stomach (see Münch. med. Woch., 1895, No. 20), because of perforation of gastric ulcer or more rarely of cancer. Most cases from ulcer occur in the left subphrenic space, most cases from cancer in the right space. In subphrenic abscess arising from appendicitis Lampe asserts that the pus either mounts up to the subphrenic cellular tissue along the cellular tissue of the mesocolon, or else abscess of the liver and subphrenic space is caused by pylephlebitis beginning in the veins of the cecum and appendix. Lampe says there is no absolutely certain sign of perinephric abscess, for Leyden's sign may be absent (gas in subphrenic pneumothorax). In suspected cases operate at once.]

The Hunterian Lectures for 1895 were delivered by Mr. Timothy Holmes[2] of St. George's Hospital. These lectures are characterized by the same features for which the writings of Mr. Holmes have always been noted. Accuracy of statement, clearness of detail, and comprehensive grasp have always been his leading characteristics as a surgeon. He presents **the experience of St. George's Hospital in celiotomy,** exclusive of gynecologic operations, from 1888 to 1894, inclusive. He was anxious to produce an unselected and continuous series of hospital cases. We are inundated in the medical papers with successful cases of celiotomy for various conditions, and from this side of things two opposite conclusions seem to be drawn: Some seem to feel that one has nothing to do but to open the abdomen and all difficulties vanish; others reflect that published cases have been published because they were successful, and if they had not succeeded would never have been heard of—that even when distinguished surgeons give their whole experience, that experience represents the practice of a specialist who is called because the case is a promising one. The unselected and complete experience of a hospital into which a man is sent, not because his case is promising, but too often because

[1] Med. Rec., Feb. 15, 1896.

[2] Brit. Med. Jour., July 5, 1895.

it is hopeless, would tell a very different story from that of private practice, because the private practitioner is obliged to reject the worst cases, while the hospital surgeon, if he does his utmost duty, takes even the faintest chance of saving life; indeed, sometimes, as in railway injuries, he has to operate without any chance of saving life, but merely to procure his patient an easier death. The cases reported are shown in the following tables:

	Cases.	Recovered.	Died.	
Injury	3	0	3	
Exploratory	5	3	2	
Abscess	11	10	1	
Peritonitis	6	1	5	
Tuberculous peritonitis	3	1	2	
Peritonitis from twisted ovarian pedicle	1	1	0	After ovariotomy.
Perforation of appendix, etc.	10	0	10	
Removal of appendix	3	2	1	
Hydatids	6	4	2	
Pancreatic cyst	1	1	0	
Hydronephrosis	1	1	0	
Uterine	2	1	1	Exploratory operations for tumors which turned out to be uterine. One recovered after hysterectomy.
Other tumors	5	1	4	
Gastric ulcer and duodenal ulcer	14	4	10	
Cholecystotomy	3	3	0	
Gastrojejunostomy	4	3	1	
Intussusception	5	0	5	
Kink and volvulus	4	1	3	
Strangulation by bands	11	4	7	
Stricture of bowels	7	0	7	
Internal hernia	4	1	3	
Gangrene of cecum	1	0	1	
Total	42	110	68	

Mr. Holmes proceeds to discuss specifically and in detail celiotomy in limited abscess, for peritonitis, fatal cases of diffuse peritonitis from perforation, for tumors, for perforated ulcer of stomach or duodenum, for intussusception, for kinking and volvulus, for strangulation by bands, and for stricture of the bowel. These tables and the comments upon them are of extreme value and are worthy of an attentive study.

Williams[1] reports a case showing the value of a **left supraclavicular adenopathy** as a revealing symptom of intraabdominal cancer. Several of these cases have been recorded by Continental observers, demonstrating the frequency of the association of the enlargement of the left supraclavicular lymph-glands with malignant disease of the intraabdominal region. Troisier first directed attention to this sign in 1888. In Williams' case the left supraclavicular lymph-glands, as well as those of the upper part of the axilla, were enlarged and hard, and thus by interfering with venous circulation had caused edema of the hand and forearm. The growth was due to dissemination of the disease through the medium of the thoracic duct. The existence of this symptom in the case completely negatived exploratory operation. The tumor was probably malignant endothelioma of the omentum.

[1] Lancet, Aug. 3, 1895.

Ramsay[1] inquires, **Why is the abdomen opened in the middle line?** He says that in text-books we find that the linea alba is almost invariably commended as the proper situation for incision, and in a few instances when it is considered wise to deviate from this incision we are told to incise the linea semilunaris. From the fact that this assertion is so dogmatically made and so universally maintained we would infer that there must be some decided advantage to be gained by opening the abdomen in either the linea alba or the linea semilunaris. The advantages which are claimed are that the vascularity is low in the middle line, and therefore the hemorrhage is light; that the structures cut through are less important; and that by either of these incisions we gain free access to all parts of the abdominal cavity. In the first point we see no advantage, really a disadvantage. Although the abdominal wall contains more vessels in other regions, there is never any hemorrhage which the surgeon cannot most readily control, and the fact that the linea alba is not vascular is an evidence that union cannot be rapid, and when permanent healing is slow in taking place hernia is apt to arise. The fact that there are no important structures is certainly not an advantage. The incision goes through fibrous tissue layers that strongly resemble each other, and makes it a matter of difficulty, especially for inexperienced operators, to know the depth of incision; and this is particularly true when inflammation is excited. It is very hard to approximate the layers accurately together, and they always adhere, so that the depth of the scar when found is barely $\frac{1}{8}$ in. thick. We notice this constantly when making an incision through a scar of an old incision. The third point, if true, would be distinctly in favor of median incision, but this claim is theoretic and not practicable, as we can obtain ready access by other incisions. One great disadvantage of the median incision is that, should it be necessary to extend it upward, the umbilicus comes in the way. The umbilicus can never be absolutely cleaned; the knife must be carried around it, or else the umbilicus must be removed. The situation which Ramsay recommends as the proper one for the incision is through the middle of the rectus muscle on either side. The parts are vascular, but the hemorrhage is arrested with the greatest ease. The muscles are not subjected to any severe injury, as the muscular fibers are separated longitudinally by blunt instruments. The incision may be carried as high up as the ribs or as low down as the pubes without any difficulty at all, as we have no umbilicus in the way to interfere with us. The layers are distinctly marked, so that it is impossible with ordinary care to wound the viscera. We have the freest access to all parts of the abdominal cavity, an excellent scar is left—one that does not pucker—and the separate layers are not coherent. When the wound is carefully closed the risk of hernia is extremely slight. The best method of closing the wound is to run silkworm-gut sutures through all the layers. These are placed in situ and held by forceps; then the peritoneum and posterior layer of fascia are brought together with fine silk sutures, either the interrupted or

[1] Lancet, Nov. 30, 1895.

continuous, and then the anterior layer of the fascia is brought together in the same way. This brings the muscle firmly into contact, maintains the original thickness of the belly-wall, and prevents coherence of the fascial layer. If there is temporary drainage required, necessary sutures are placed in situ and marked with knots. These can be tied accurately when the tube is withdrawn. Ramsay has used this incision in 5 cases, and has found that the advantages claimed for it are real and not theoretic. He thinks that all students should be taught that there is one place where the abdomen should not be opened; that is, the linea alba.

Clubbe[1] discusses the question of **celiotomy for intussusception in very young children.** He reports 7 cases. The oldest case was not over 6 months of age. Of these, 4 made a good recovery. Clubbe says that very young children bear the shock of celiotomy extremely well. Whereas it is true that many cases may be relieved by the use of injections of water or air or oil, this treatment contains certain elements of danger. It is impossible to regulate exactly the amount of pressure, and if any ulceration exists in the bowel, rupture may occur. Clubbe thinks that celiotomy should be done in every case when the surgeon is sure that he has to treat an intussusception which cannot be reduced by moderately forcible rectal injections. He did not drain any of these cases subsequent to operation. [Most cases of intestinal obstruction in children are due to intussusception, and in a majority of them the attack begins with great suddenness. The ileocecal form is the most common, though either the colon alone or the small intestine alone may be involved. Injections can be best given when the patient is anesthetized and in the knee-chest position, but they should only be tried very early in the case (first 24 hours). A method of operating devised by Paul will be found in the *Year-Book* for 1896, page 224.]

Rydygier[2] has studied the cause of **intestinal invagination** and has investigated the records of 84 cases. He holds that if nonoperative procedures have been tried and failed, operation should at once be resorted to. When we do a celiotomy and the intestine seems to be in good condition, we should pull apart the invagination; but if the intestine looks suspicious, the peritoneal cavity should be packed off with iodoform-gauze or the suspicious portion of the intestine should be drawn outside of the belly-wall. If it is found impossible to pull apart the invagination, resection should be practised, and when the sheath of the invagination is profoundly altered the entire invagination should be resected. He does not believe in the practice of an enteroanastomosis, and holds that an artificial anus is only to be made in case there is collapse. In case of chronic invagination we may employ medical treatment and nonoperative methods for a week, but if they fail up to this period, they should then be abandoned. Celiotomy should be performed and resection practised. The presence of a great many adhesions may justify enteroanastomosis. The formation of an artificial anus should not be thought of. [In speaking of operations upon infants we recall that Bogert operated

[1] Australas. M. Gaz., No. 10, 1895. [2] Beiläge z. Centralbl. f. Chir., 1895, No. 27.

successfully for intussusception upon a baby 4 months of age,[1] and that Carpenter operated successfully upon a baby 2 months old.[2] In each case celiotomy was performed.

How large a number of cases of obstruction are due to intussusception is shown by the statistics of Lichtenstein and Bryant. In 1652 cases of obstruction, excluding hernia, 657, or about 40%, were due to invagination. In 593 records compiled by Lichtenstein it was noted that 131 of the patients were under 1 year of age.

The best rule to follow in these cases when they are acute and recent is to etherize, make one attempt to relieve by injection, and, if this fails, at once do celiotomy, pulling apart the invagination if possible, and if this is not possible resecting the intussusceptum.]

Golding-Bird,[3] concerning **skin-bridging in inguinal colotomy,** tells us that Mr. Bidwell[4] described a method of ensuring free exit of feces from the upper opening of the bowel after inguinal colotomy, and at the same time of preventing recession of the gut into the abdomen. His method consists in bringing the upper lip of the skin-wound through an opening made in the mesosigmoid and attaching it to the lower lip of the wound. The bowel is thus placed over a bridge of skin instead of one of glass or rubber, as used to be employed. Golding-Bird endorses all Mr. Bidwell says in favor of this proceeding. The operation is rapid, it is unnecessary to suture the bowel to the parietal peritoneum, and in most cases only 1 suture is needed to fasten the bridge of skin. Golding-Bird did it in 2 cases with gratifying success. [We have used it in several cases, and find it easy of performance and satisfactory in result. The surgeon must of course be sure which is the lower end, for to constrict the upper end would be unfortunate. It seems to us that the word "colostomy" is the correct designation of the operation, and not "colotomy."

The operation of iliac colostomy is preferable to lumbar colostomy. Deansley truly says that colostomy should not be performed without first locating the obstruction. Accurate localization is often impossible without first opening the abdomen: the abdominal incision preliminary to iliac colostomy permits of determining with accuracy the seat of constriction. Lumbar colostomy is only permissible when the seat of obstruction is definitely known, but even when performed with care the lumbar operation does not completely divert the fecal current. The lumbar operation, in our opinion, should no longer be performed.

In a mere preliminary opening of the bowel, or colotomy, the portion of bowel should never be fixed outside, as in colostomy. Deansley says when a temporary opening is desired we should simply make a fecal fistula. This is done by opening the cecum, inserting into it a small tube, returning the cecum into the belly, and keeping it in contact with the abdominal wall by traction upon the tube and several stitches fastening the bowel and parietal peritoneum, but never the bowel and skin.[5]]

Stephan's[1] patient had labored under an obstinate dysentery which drugs had absolutely failed to relieve. He determined to establish an **artificial anus,** and applied local treatment through this opening. The case was cured of the dysentery, and in a few months the artificial anus was closed by operation.

DISEASES OF THE PANCREAS AND SPLEEN.

Leith[2] presents a study of **rupture of the pancreas.** He makes one group of cases in which death very quickly followed the injury, the symptoms being simply shock and collapse, and no symptom existing which pointed to pancreatic lesion. There were no lesions upon the surface of the abdomen, and this proves that diagnosis without exploratory incision is impossible. A vertical incision about 3 in. long should be made in the mid-line or a little to the left of the mid-line in the epigastric region, which will enable the surgeon to explore the anterior surface of the pancreas most satisfactorily. He tells us that if we introduce an electric lamp inside of a Fergusson speculum, we shall be enabled to inspect the pancreas and its peritoneal covering. The usual cause of death in these cases is hemorrhage. Serious lesions of other viscera are, as a rule, present, and treatment must be entirely symptomatic if any exploratory celiotomy is not undertaken. After an exploratory celiotomy hemorrhage may be arrested by pressure and the application of sutures passing through the peritoneum covering the gland alone; these sutures will bring the ruptured ends of the pancreas together. It should be remembered that the pancreatic peritoneum is closely adherent to the gland, and that there is no fat or any other structure between it and the gland. Hence peritoneal sutures will approximate the separated surfaces of the pancreas. One trouble in this procedure is that blood or pancreatic juice is liable to accumulate between the two surfaces, separating these surfaces and leading to cyst-formation.

Senn made a number of experiments upon animals, and came to the conclusion that the two sides of the wound in the pancreas should be ligated separately before the peritoneal sutures are applied. This will arrest the hemorrhage, prevent accumulation of pancreatic juice, and closely approximate the two surfaces. Slight cases of pancreatic rupture occasionally happen, and it is quite likely recover. In fact, autopsies have proved this. An injury in the epigastric region may be followed in a greater or less time by a pancreatic cyst. In a table which Leith publishes one cyst appeared as early as 10 days after the injury, and the other did not appear for 8 years. Leith's table contains the records of 17 traumatic cysts.

Cathcart has explained the formation of the cysts as follows: The laceration of the pancreas due to injury leads to extravasation of blood, and this blood is mixed with the secretion of the pancreas from the lacerated ducts. We thus have a hematoma, to which is constantly added pancreatic fluid. This fluid must be somewhat irritant, and this tends to cause the formation of a capsule. These cysts have been treated by aspiration, but this method is

[1] Berl. klin. Woch., 1896, No. 1, p. 21.

[2] Edinb. Med. Jour., Nov., 1895.

not curative, and is very dangerous, as the cyst almost certainly refills, and the injection of irritant fluids is liable to cause a fatal peritonitis. These cases should be treated by celiotomy. The cyst should be lifted forward and incised, and a pancreatic fistula established to maintain drainage. This fistula after a time heals. There are 17 cases on record in which this method was employed, and in 16 of them it was successful. Krecke says that out of 27 cases treated by incision and drainage, all recovered, but in those cases in which the cyst was dissected out 3 died. The method of anterior incision and drainage fails to cure some few cases. It is most applicable to movable cysts, which come forward readily from the anterior abdominal wall, but is not so applicable to those cysts very broad posteriorly and not very movable. It is difficult to reach such a cyst to incise it from the front, and it is not easy to bring it forward to the abdominal wall. Cathcart and Littlewood have maintained that in these cases a posterior counteropening can be made with the greatest ease. Leith came to the conclusion that cysts might be reached by a primary posterior operation. This can be very easily performed upon the cadaver. A vertical incision 3 in. long is made at the outer border of the left erector spinæ muscle, the incision beginning just above the 12th rib. After reaching the upper border of the quadratus lumborum muscle the finger is pushed above it, and finds the posterior surface of the kidney and accurately locates the situation of the renal vessels. We know that the tail of the pancreas and the posterior and outer wall of the lesser omentum lie just above and just inside these renal vessels, and by inserting a probe we can enter the sac of the lesser omentum easily, either through the mesocolon below the inferior margin of the pancreas or through the posterior layer of the peritoneum above the pancreas. There is no likelihood of injuring the suprarenal capsule or any other adjacent structure. When fluid was contained in the sac of the lesser omentum the finger could distinctly make out fluctuation, and the fluid could be most readily evacuated by pushing a drainage-tube into the sac of the lesser omentum just above and just inside these renal vessels. This procedure would be just as easy in the case of pancreatic cysts. Cotterill adopted this method of reaching a pancreatic cyst in the cases which he had in his charge. He entered the cyst below the vessels of the kidney, and the patient made a good recovery. Other operators have adopted the posterior incision for fluid to drain the sac after finding it by the anterior incision. Gould had such a case, in which when he made the anterior incision he was unable to bring the cyst to the surface, and therefore made a posterior incision and drained. The fistula closed rapidly. If the posterior incision had been used at first, the cure would have been equally successful. Leith strongly recommends the posterior incision. It is very easy of performance, has great advantages over the anterior incision, affords far more perfect drainage, and hence secures much more rapid convalescence. Even if the surgeon fail to reach a cyst by a posterior incision, it would in no wise interfere with the subsequent anterior incision, and would even in such cases permit the establishment of posterior drainage.

Sutton[1] records 3 successful **splenectomies.** [It is considered proper to remove the spleen in some cases of hypertrophy (simple or malarial), of floating spleen, injury, abscess, cystic disease, and malignant disease. Most authorities condemn the operation in cases of leukemia, because of the great mortality. In wandering spleen better results have been obtained by splenectomy than by fixation. In operations upon the spleen the great dangers are shock and hemorrhage. Shock is often inordinate, and traction upon the pedicle greatly aggravates, because, it has been said, of pressure upon the splenic nerve plexus. The excessive hemorrhage is in some cases due to hemorrhagic diathesis, which condition is sometimes associated with enlarged spleen (Mosler).]

Spanton[2] writes a paper upon **Splenectomy,** and presents the notes of 3 cases. The first case was one of simple hypertrophy of the spleen in which death occurred from hemorrhage 5 hours after operation. The second was a case of simple hypertrophy in which death from shock occurred 11 hours after operation. The third was a case of simple hypertrophy in which operation was followed by recovery. Spanton says that splenectomy has now been performed sufficiently often to enable us to estimate its sphere of usefulness.

In 25 cases of leukocythemia only 1 recovered, and splenectomy in this case should not be performed; 38 cases of hypertrophy showed 20 deaths: these are the cases which most often present themselves to the surgeon. The mass drags on the stomach, makes pressure on adjacent organs, occasionally sets up local peritonitis, and usually renders life intolerable. A solid tumor causes a much greater amount of discomfort than does a fluid tumor of the same weight. Taking 3 decades, we have this remarkable result: from 1865 to 1875 the mortality of splenectomy was 80%; from 1876 to 1885 it was 45%; and from 1886 to 1895 it was 20.68%. He thinks that for wandering spleen we should adopt the operation of splenorrhaphy, as he would prefer it to the greater risk of splenectomy. The chief risks of the operation are shock and hemorrhage, and in the large proportion of the cases both of these conditions have been met. We easily understand why shock should be formidable from the close connection of the spleen with the solar plexus, but in most of the recorded cases we find shock was first noticed when the attempt was made to remove the organ from the abdomen. In his own cases this was most marked the minute the spleen was pulled upon in the slightest degree. In his last case he was so struck by this fact that it occurred to him that it might be caused by dragging on the diaphragm. Influenced by this idea, he decided to begin by dividing the suspensory ligament. This was transfixed, ligated, and set free, and the minute this was done all signs of collapse or shock passed off. He thinks that beginning with this suspensory ligament makes the rest of the operation easier, and that this method should always be adopted when possible. In most of the cases the suspensory ligament has been dealt with last. As to securing the vessels, no general rule can be laid down, though when possible the splenic artery and vein had best be ligated separately. In many cases the vessels divide before they reach the spleen,

[1] Lancet, No. 3764, 1895.

[2] Brit. Med. Jour., Nov. 2, 1895.

and we have a very broad pedicle with many vessels to be dealt with. [The suggestion that shock may be due to traction upon the diaphragm, and hence that the suspensory ligament should be first dealt with, is extremely important. The author differs from many writers in advocating the operation of splenorrhaphy.]

Plucker[1] of Cologne writes an article upon **Splenopexy for Wandering Spleen.** The old treatment was extirpation, which he tells us is a procedure as irrational as would be the operation of nephrectomy for a faulty kidney. Rydygier first advised that the organ be firmly anchored in its proper situation. This procedure is far safer than splenectomy, although it contains certain elements of risk: the operation is difficult and the fixation is not certainly permanent. [We must remember that in these cases splenectomy is very successful and is permanent.] Plucker cites a case of Bardenheuer's in which, instead of anchoring the spleen by intraperitoneal sutures as in the plan of Rydygier, it was fixed outside the cavity of the peritoneum in the subperitoneal tissues. The spleen was forced through a small opening in the peritoneum; the parietal peritoneum was then sutured to the peritoneal coat of the pedicle, and thus communication with the peritoneal cavity was closed. To anchor the spleen a suture was passed round the 10th rib and also through the lower end of the viscus. A number of smaller sutures were employed to fix it to the fascia and connective tissue. The case went on to a favorable conclusion. The incision employed by Bardenheuer consisted of 2 lines, 1 running longitudinally from the 10th rib to the iliac crest, another taken off at right angles from the upper extremity of this incision. He thus formed a flap composed of skin and muscles which could be freely detached.

Douglas[2] of Vanderbilt University considers **splenectomy statistically,** and reports a case. The statistical table is very thorough and valuable. The reported American operations are 29 in number, with 11 deaths.

Douglas speaks of echinococcus of the spleen, and discusses 6 cases with 4 recoveries; 5 cases of primary sarcoma with 2 recoveries; leukemia, 36 cases with 5 recoveries. The successful operators for leukemia were Assaky, Ceci, Landfois, Franzolin, and Hartman. The table shows 40 cases of malarial hypertrophy with 24 recoveries, and to this list Douglas adds a successful case of his own. In 59 cases of simple hypertrophy there were 34 recoveries, a mortality of 42%; 3 cases of simple cystoma, all of which recovered; 3 cases of primary nontraumatic abscess and sloughing with 3 recoveries; 2 cases of floating spleen treated by splenectomy, with 1 recovery; wounds of spleen show 43 cases with 42 recoveries (in 8 of these only the part protruding was removed). As long ago as 1700, Taritoni removed the spleen. [Mosler has gathered records of 15 cases of splenic echinococcus which were aspirated; 6 died, 6 recovered, and 3 are unrecorded. Trinkler estimates the mortality at 21.7%. Hahn has collected 7 cases in which splenectomy was performed for hydatid disease, and 2 of these cases died. Splenectomy for hydatid disease is a safer operation than aspiration.]

DISEASES OF THE LIVER AND GALL-BLADDER.

Rupture of the Liver.—Bryant[1] says that severe collapse follows rupture of the liver, and this severe collapse and a history of injury to the right side of the abdomen or thorax might suggest the lesion, but there are no symptoms which definitely point to it. Bryant quotes from cases which definitely prove this assertion. Had such a condition been even thought of in some of these cases by the surgeons in attendance, recovery might have been obtained instead of death. Cases of limited rupture of the liver are quite capable of recovery. This is shown by a specimen in the museum of Guy's Hospital which was taken from the body a week after injury. When recovery follows limited rupture of the liver the case is generally supposed to have been a local traumatic peritonitis. Severe laceration of the spleen is likely to produce death from hemorrhage, although a limited laceration may be recovered from, and may be looked upon as a case of local peritonitis, but in every case of injury in the left side of the abdomen or thorax the surgeon should think of the possibility of rupture of the spleen. Bryant then makes some observations upon rupture of the stomach.

Slaughter[2] reports a case of **amebic abscess of the liver** in a child, and comments upon the extreme rarity of these abscesses in children even in the tropics. His case makes the 27th which has been recorded. The rarity of these abscesses in children is shown by the statistics of Rouis in Algiers, who had only 1 case in a child in 250 cases of abscess. In 9 cases injury was supposed to have been the cause, although this was not proved to have been the fact. The author's case died in spite of operation.

Abscess of the Liver.—Hermes[3] furnishes a contribution to the surgery of the liver, and reports 4 cases of abscess of the liver, 2 of which were previously reported by Sonnenburg. He also reports 2 cases of stone in the common duct, and 1 case of enormous thickening of the walls of the gall-bladder. In 1 case the abscess arose in the liver some months after an attack of appendicitis. It is absolutely certain that purulent appendicular disease is liable to give rise to abscess of the right hepatic lobe. This is an argument in favor of the removal of the appendix. In a case cited by Hermes abscess developed a few months after a perityphlitis. This is not the usual rule, as secondary abscess after appendicitis usually presents multiple foci of suppuration in the liver. Fränkel's diplococci were found in the pus. The 2d case of liver-abscess was due to gall-stones. The author considers exploratory openings into the liver and gall-bladder as dangerous, in that they may give rise to septic peritonitis. Of course if the liver is adherent to the abdominal walls it is the easiest thing in the world, and one of the safest, to open the abscess, but if there are no adhesions, the abdominal cavity must be shut off by the use of iodoform-packing until adhesions form. In his first case of stone in the ductus choledochus he broke the stone up by the finger and

[1] Lancet, Nov. 9, 1895.

[2] Va. Med. Monthly, No. 7, 1895.

[3] Deutsch. Zeit. f. Chir., No. 6, 1896.

pushed it into the duodenum. This is a procedure to be always tried, and which will be successful if the stone is soft and if the walls of the ductus choledochus show a fair amount of resistance. If we are unable to break up the stone, we may open the gall-bladder or directly cut the duct, remove the stones, and suture the wound. This was done in his 2d case, which died. Here the duct, enormously dilated, was supposed to be the gall-bladder, and the mistake was discovered on the postmortem table. This patient died because of hemorrhagic diathesis, which is a fearful and not unusual complication of grave icterus.

Fenger's article upon "**Stones in the Common Duct,** and their Surgical Treatment"[1] is a masterly production worthy of careful study. The medical aspects of this important paper are reviewed in another section by Drs. Pepper and Stengel (p. 181). Fenger reports 6 cases, and gives in detail the treatment of each one.

He tells us when attempting to outline the field of operation for the common duct we must remember we are dealing, not with a normal, but with a dilated duct. He uses a specimen to explain the relation of the structures in the hilus of the liver, and says the conditions about to be described are those generally found. The organ is described as in the position in which operations are made (patient upon his back and anterior border held up until its position is almost vertical). The vessels, bile-passages, and duodenum of the specimen were injected with colored paraffin. He describes the anatomical relations in detail, and then discusses the operation. The operation is explained at length, and every surgeon ought to make a study of this paper.

Magill of Paris and Jourdan of Marseilles[2] make an elaborate study of **choledochotomy,** considering in detail the reported cases and discussing the different methods of procedure in operations for gall-stone, and concluding with general considerations, an estimate of the mortality, and an elaborate explanation of the operative technic. In 72 cases of choledochotomy there were 50 recoveries, a mortality of 30.55%. Operations done in extremis and cases in which the death was due obviously to the loss of function of the liver should not be placed in the statistical table, and if these cases are deducted the mortality is reduced to about 20%, which represents the actual operative loss. This estimate, however, includes deaths from such accidents as greater familiarity with the operation and care which can be taken when forewarned will enable future operators to avoid. A mortality of much less than 20% can with safety be expected from this operation in future. Every incision of the anterior abdominal wall that could expose the liver-ducts has been used by some one for this operation. The incision most frequently employed is the vertical one upon the left border of the right rectus. Some operators have made a median incision, obliquely curved and parallel to the costal arch. Others have used a transverse incision, others various incisions. The vertical incision on the external border of the right rectus itself exposes the gall-bladder in its normal position, but the common duct lies nearer to the middle

[1] Am. Jour. Med. Sci., Feb., 1896. [2] Internat. Med. Mag., Apr., 1896.

line. The oblique transverse incision parallel to the edge of the liver exposes both the gall-bladder and the common duct, but it has the great disadvantage of cutting the abdominal muscles transversely, rendering the subject liable to hernia in the future.

In some cases, through an error of diagnosis, the gall-bladder has been brought through the lumbar incision. This incision is extremely inconvenient, and gives access to the retroduodenal and pancreatic portion of the common duct alone. The fact alone that we find it necessary to always examine the gall-bladder and the bile-ducts renders this incision absolutely inappropriate. The T-incision gives easy access to the lower surface of the liver, but there is danger of subsequent hernia. In case of need a transverse section of the rectus may be added to the vertical incision, but at the beginning of the operation it is best to employ only a long vertical incision, either median or lateral. The median incision from the ensiform cartilage to the umbilicus corresponds to the anatomical position of the common duct, and it allows deeper access to the lower surface of the liver; hence an intervention limited to the common duct would make a median incision preferable, but the operation under ordinary circumstances is performed for chronic jaundice attributed to stone, but with no indication as to whether we shall be obliged to operate on the gall-bladder, upon the common duct, or upon both. Therefore the authors decide in favor of the vertical incision on the outer border of the right rectus, descending from the costal arch for a distance of 12 to 15 cm., and if this incision is found to be too small, a transverse section of the rectus may be added to it. They then discuss the treatment of adhesions, which are very commonly extensive in gall-stone disease, the bladder being apt to adhere to the colon and duodenum and sometimes to the stomach; there is constant adhesion between the liver and the omentum and transverse colon, which must be separated first. Finding the notch in the edge of the liver points to the probable site of the gall-bladder. Liberation of the structures should be accomplished by the finger, aided, it may be, by the knife and scissors. We should take great care not to open the colon, duodenum, or stomach—not to cut unexpectedly any fistula existing between the bile-passages and the other viscera. Surgeons should always remember that the vermiform appendix may be found abnormally in this position.

The first effort is now made to find and examine the common duct. The edge of the liver, protected by a sterilized towel, is lifted with a spreader in the hands of an assistant at the left of the operator, while a second assistant, opposite, having covered the stomach and intestines with sterilized towels, with the right hand pulls the stomach to the left, at the same time depressing the intestines with the other hand. The inclined plane position here enables the surgeon to see much better. The surgeon then places his left fore finger on the gall-bladder and the cystic canal, descends to and enters the foramen of Winslow, and hooks the right border of the gastrohepatic omentum, the common duct, the vena porta, the hepatic artery and ganglia, all of which the finger draws downward and forward. The thumb of the same hand, or more

conveniently the right fore finger, then follows from the anterior surface of the pedicle of the liver, examining carefully all the mass from the liver to the duodenum, the hepatic duct, the mouth of the cystic duct, and the supraduodenal part of the common duct. This methodical palpation will almost certainly detect any stone which may be present. To complete the examination of the common duct, search for stone in the retroduodenal and pancreatic portions, which is also done by digital palpation. The left fore finger is withdrawn from the foramen of Winslow, passed to the right of, and, as far as its mobility allows, behind, the duodenum, which it compresses as much as possible to approach the common duct. The left thumb or the other fore finger then compresses the parts against the posterior digit, and in this way explores for stone behind the duodenum and pancreas. We must not mix up a calculus with ganglia which exist in this region. For surgical considerations the common duct is divided into 2 parts—the 1, supraduodenal, A, attainable above the duodenum; the other, B, situated behind the duodenum and pancreas. Most calculi will be found in the first portion. This part is exposed by drawing down the duodenum, and corresponds to the right border of the gastrohepatic omentum a little below and in front of the foramen of Winslow. The vena porta lies to the left and behind the common duct, while to the left and in front of the vena porta lies the hepatic artery, from which the right gastroomental passes downward behind the first part of the duodenum. This portion of the duct is frequently crossed in front by large veins which may be injured.

"The common duct, in its normal condition a small canal of 5 to 6 mm. caliber, closely following the vena porta, differs widely from the duct; in cases of calculus stenosis, in which the biliary retention has almost invariably produced a large dilatation of the duct, its walls are usually thickened. The situation of the stone well determined, and the other viscera drawn aside and protected by aseptic towels from any possible contamination from the gall, the incision of the common duct is made longitudinally, but directly upon the calculus, which is the only guide for the cut. For this maneuver the left hand plays an important part, being introduced by the foramen of Winslow, passed behind the common duct, which it holds fixedly, and at the same time pressing forward the contained stone, assuring its immobility. Sometimes, however, the mass of adhesions allows the insertion of only the left fore finger to fix the stone, while the knife cuts the wall of the duct. The incision is often followed by a more or less severe hemorrhage of venous origin, rapidly stopped by compression. The edges of the incision may be maintained open by pressure-forceps, or by loops of thread such as Lauenstein places in the walls of the duct before its incision, which serve him later for a complementary suture.

"The extraction of the stone through the cut must sometimes be aided by a director or curet in order to detach the adhesions of the calculus to the wall of the duct. Sometimes even crushing must be resorted to, and the extraction be accomplished by the removal of the pieces. By the same incision other calculi, included and movable in the duct, can also be extracted."

The authors discuss the stones in the common duct, in the retroduodenal and pancreatic portions of the common duct, catheterization of the common duct and suture of its incision, drainage, suture of the abdominal wound, dressings, and results. Of results they speak as follows:

"*Post-operatory Results.*—A choledochotomy without complication generally gives a rapid, uneventful recovery. A few days after the operation a slight flow of bile from the drain may be observed, which either ceases almost immediately or results in a biliary fistula, closing some weeks later. The stools of the patient are found normally colored by the biliary secretions almost immediately after the operation. The jaundice disappears rapidly, but the liver may long remain of increased volume. If the operation is followed by a cholecystostomy, it is remarkable to see how soon the flow of the bile from the open gall-bladder ceases with the reestablished permeability of the common duct.

"The calculous tendency requires dietary precautions that should be indicated for the patient's future guidance.

"*Permanent Results of Successful Operations.*—As is usual for this heading, the lack of details to be obtained for its study is deplorable. Of the 72 clinical histories, only 27 follow the patient beyond the recovery from the operation. Küster (Case IV.) mentions the reappearance of heptic colic 5 months after the choledochotomy—colic which a cure at Carlsbad, the next year, relieved by the evacuation of 2 calculi. It will be noted in this case that the nondilated gall-bladder was not opened during the operation, and it may be possible that here were hidden the small concretions which may have formed the nuclei of the stones subsequently eliminated; 26 patients were reexamined after the choledochotomy, 7 within the first 6 months, 6 between 6 months and 1 year, 4 at the end of 1 year, 1 after 15 months, 1 16 months, 2 18 months, 2 20 months, 2 21 months, 1 3 years, and 1 4 years after the choledochotomy, and in all the recovery is noted as complete and permanent."

Elliot[1] commends **immediate suture of the gall-ducts** after extraction of stone. He gives a series of cases. He believes that the operations of cholecystotomy and cholecystenterostomy have become too much routine practice, and he strongly believes that incision of either the ducts or the bladder should be followed in the majority of cases by immediate suture. He has performed 5 such operations—1 on the hepatic duct, 1 on the common duct, and 3 on the gall-bladder. All have been successful. He reports these cases in detail. He says that a few years ago cholecystotomy was considered a satisfactory operation and Tait's success was considered wonderful, but we now find that immediate suture of the gall-bladder is quite as safe, frequently more satisfactory. Heussner has done this operation 13 times with good results; Körte reports 5 cases which have recovered; Abbe, Richardson, and others have reported successful cases. In late years it has been rare to find a report of a bad result from leakage. In fact, there seems to be very little real danger of this accident when the common duct is clear and the walls of the gall-bladder are moderately healthy, and it is only in such cases that we should employ immediate suture. Langenbuch believed that gall-stones were formed in the gall-bladder, and he suggested the operation of cholecystectomy for the radical cure of the formation of gall-stones. We now know that the nuclei of stones are formed in the liver, and therefore cholecystectomy is not a radical cure for lithiasis, and is only applicable to cases of malignant disease or of a very severe inflammation of the gall-bladder, or when the cystic duct is irremediably closed. Stones in the cystic duct have usually been removed by forceps through the gall-bladder, but there is always danger of forcing the

[1] Ann. of Surg., July, 1895.

stone into the common duct, and there are cases on record in which the stone has been forced into the hepatic duct and never recovered. In some cases pushing the stone up by squeezing the duct with the hand or with forceps through the gall-bladder has been successful. Incision of the duct is greatly preferable to prolonged manipulation with either hands or forceps.

Kehr reported 7 cases in which he incised the cystic duct, removed impacted calculi, closed the duct with sutures, and did at the same time cholecystotomy for drainage of the duct as well as to prevent back-pressure of bile. If stones in the hepatic or common ducts are small or soft, they should be crushed between the thumb and fore finger or be pushed into the duodenum and back into the bladder. Breaking up a stone with a needle or with padded forceps has been done successfully, but it is a method which might seriously injure the duct. It is necessary to employ this method, however, when the duct cannot be raised enough to employ sutures.

Elliot gives a resume of the cases in which stones have been removed by suture of the cystic duct. Including Elliot's own cases, there are 21 cases with 5 deaths, and including Kehr's cases of suture of the cystic duct, there are 28 cases, making a mortality of less than 18%. In 5 of the cases bile leaked through the stitches, but only 1 of these died. Gauze drainage was used in all of the cases but 3.

[Küster, Rehn, and Marcy closed the abdomen without drainage, with recoveries, but Küster had leakage of bile from the abdominal wound. In 7 cases the gall-bladder was left open 6 times by a cholecystotomy and once by a cholecystenterostomy. The operation of cholecystenterostomy has been done altogether too frequently of late. The invention of the Murphy button has enabled surgeons to greatly reduce the mortality of this operation, and as a result we have largely lost sight of the main purpose of the operation, which is to restore the ducts to their normal condition. In many of these cases that have been reported no attempt was made to remove the stones, and the ducts were not even examined. Stones in the duct when left untouched, even when the pressure of bile is removed, continue to cause cholangitis. They may cause processes of ulceration. Some of the stones loosen and come out, but, on the other hand, they are often impacted and held by cicatricial stricture. If the stone should loosen and come away and leave the ducts clear, it is much better that the patient should not be left with the gall-bladder opening into the intestines, as there is then greater danger of intestinal bacteria infecting the liver. The operation of cholecystenterostomy should be limited entirely to cases in which there is an irremediable stricture of the common duct. In all cases where the duct has been incised and cannot be sewed or is imperfectly sewed, or where the stitches are found to cut because of the friable condition of the duct, a cholecystotomy ought to be joined with an operation upon the duct in order to prevent distention with the bile. Cholecystotomy should always be done when the condition of the bile-passages indicates the necessity for drainage, as in empyema of the gall-bladder and in suppurating cholangitis. Nevertheless, in ordinary conditions due to obstruction recovery without drain-

age is prompt. In those cases in which a person with gall-stones is in a critical condition it is often wise to do a preliminary cholecystotomy.]

Barker[1] presented the records of 3 cases of **operation upon the gall-bladder for stone.** In the first 2 cases the stones were removed with the greatest possible ease. Case 3 exhibited a not unusual difficulty—that is, when the gall-bladder lies deep and is immovable, and it is difficult or impossible to lift it up into the abdominal wound. Barker says in such circumstances pack iodoform-gauze around the swelling before incising it, and if the bladder will not come up to the peritoneum, the peritoneum itself must be stripped from the rectus sheath, pressed down to the gall-bladder, and stitched to it, as advised by Mayo Robson. But even this is insufficient to shut off the peritoneum in some cases. In such cases he follows the method of Robson and draws the omentum into the opening remaining, and stitches it there to close it. He believes in the method of drainage employed by Körte of Berlin. A piece of drainage-tube is inserted into the gall-bladder, the opening in which is sutured to the tube. The wound is closed around the drainage-tube and covered with gauze, and the projecting portion of the tube is united by means of a bit of glass tube with a long rubber tube which terminates in a feeding bottle by the patient's side. This mode of drainage keeps the dressings free from bile and obviates the necessity for frequent change. So soon as the bowels act and we find that the motions contain the normal amount of bile, the tube to the gall-bladder may be removed, and the biliary fistula will not usually result. [Cathcart's siphon drain might be used with advantage in these cases.]

Morison[2] reports a series of cases of **gallstone operation** done by a method which he has suggested. He maintains that it is absolutely necessary in such operations to drain a peritoneal pouch which he was the first to describe. This pouch is found beneath the right hepatic lobe, and is separated by natural barriers from the remainder of the peritoneal cavity. He says that this pouch can be efficiently drained through an opening into the abdominal wall near the lower end of the kidney, and he prefers the transverse incision to the vertical incision in operating for gall-stones. It gives better access and is less liable to be followed by ventral hernia. He does not suture the gall-bladder to the abdominal wound, except in special cases. It is liable to empty into the pouch, but this does not matter if the pouch is efficiently drained. When the gall-bladder has been closed by sutures and returned into position, a drain is left in this pouch until the surgeon is sure that the wound in the gall-bladder has united. When the gall-bladder is returned without suturing we simply drain this pouch. The author strongly believes in the removal of stone from the cystic duct by incision of the duct. [Morison's original paper describing this pouch will be found in the Brit. Med. Jour., Nov. 3, 1894. It is often a problem in the mind of a surgeon to determine whether a case of cholelithiasis should be treated medically or surgically. Gersuny has laid down the following indications for operation:

[1] Lancet, Jan. 25, 1896.

[2] Ann. of Surg., Aug., 1895.

When there is danger of rupture of the gall-bladder; when there is beginning sepsis; when there is intestinal obstruction; when the attacks of colic are frequent; when jaundice is persistent; when pain is constant and the patient cannot follow his occupation.[1] Alexander Ferguson in commenting upon Gersuny's rules[2] says the surgeon should also make the following inquiry: When should we open the abdomen to explore the gall-bladder? He thinks this should be done—1. When, after an attack of colic, a distended bladder suddenly diminishes in size, with relief of pain, but without stones in the stools, and with tenderness remaining over the gall-bladder (this means that a stone was wedged in the cystic duct, but has fallen back into the bladder). 2. For jaundice following colic. 3. When tenderness persists. 4. When marked enlargement persists. We do not think it advisable to persist long in medical treatment. After a careful trial, if improvement is not noted, operation should be performed. To delay operation opens the patient to the dangers of perforation, suppuration, and, Mermann says, cancer. The best operation is immediate suture of the bladder, but this is not safe if the contents of the viscus are septic.]

Terrier[3] in a paper upon "**The Treatment of Angeiocholitis and Cholecystitis of Infectious Origin**" reviews the different plans of treatment which have been suggested. He tells us that if the biliary ducts are inflamed, whether calculi exist or not, and the patient has attacks of fever, either continuous or remittent, celiotomy must be performed, this celiotomy having for its purpose the incision of the gall-bladder and the making of a biliary fistula. This operation enables the surgeon to explore and gives thorough drainage to the septic bile and free exit for the bile products, and permits, in a certain indirect and mechanical manner, the disinfection of the bile-ducts. [Block's method of cholecystotomy is a safe one when the above conditions exist. It obviates the danger of septic peritonitis, and does not favor the anchoring of the bladder by dense adhesions which would be a trouble in subsequently closing the fistula. Block performs extraabdominal cholecystotomy. He opens the belly, draws the gall-bladder through the wound, and fastens a portion about as large as a hen's egg outside of the belly-wound. When the peritoneal cavity becomes well guarded by adhesions the gall-bladder is opened. It is sutured at once if protracted drainage is not needed and after union occurs. The viscus is separated from the belly-wound, and is dropped back into the abdomen. (See Rev. de Chir., Feb., 1895.)]

Ferguson[4] says that **biliary fistula** frequently follows operations upon the gall-bladder because surgeons stitch the gall-bladder directly to the skin, and thus secure a mucocutaneous tract which is very difficult to heal. Another operative cause is that the gall-bladder is occasionally sutured to the lower angle of the abdominal wound. The most dangerous cause of biliary fistula is the obstruction of the cystic or the common duct by gall-stones or by stricture. The treatment of biliary fistula is preventive and curative.

[1] Wien. med. Presse, No. 47, 1894.
[2] North Am. Pract., July, 1895.
[3] Rev. de Chir., Dec., 1895.
[4] Chicago Med. Rec., Sept., 1895.

When the surgeon performs a cholecystotomy and the ducts are found patulous or if they were obstructed by calculi, the calculi are removed and permanent fistula is prevented by suturing the incised gall-bladder to the peritoneum alone at the upper angle of the wound. It must not be sutured to the skin. When it is sutured to the peritoneum alone it leaves the organ within the abdomen in the best possible position for closure. When we come to treat an existing fistula we should perform a plastic operation, making incision through the skin and through tissues about the fistula down to, but not through, the peritoneum. The abdominal cavity is not opened. The mucous tract is amputated and the gall-bladder is closed with 2 rows of catgut suture, the first row of interrupted sutures to coaptate the mucous membrane and check hemorrhage, and the second row of inversion sutures inverts the first row. When this has been done it will be found that the gall-bladder recedes into the abdomen to an astonishing degree. The operation is completed by closing the abdomen in the usual manner. Ferguson then cites a successful case in which he did a plastic operation for a biliary fistula which followed a cholecystotomy. He has been able to collect only 14 cases, besides his own, where attempts were made to close biliary fistulæ by operation, and he appends a statistical table containing them.

GENERAL OBSERVATIONS CONCERNING ABDOMINAL SURGERY.

Treves[1] writes on the treatment of **Glenard's disease by abdominal section.** This disorder, known as abdominal ptosis, visceroptosis, or Glenard's disease, was first described by Glenard of Lyons in 1885. It depends upon a relaxation of the abdominal wall and of the supporting ligaments of the viscera, as the result of which the organs drop to a lower level in the abdomen. The affection is most common in women. There is no definitely assigned cause, though repeated pregnancies, overexertion, and injury may all play a part. The first part to descend is the right band of the transverse colon; then the stomach is drawn down, with the result that the pyloric opening is compressed and the passage of food is hindered. In course of time the rest of the transverse colon descends. The orifice between the duodenum and jejunum is narrowed, and a further obstruction is offered to the passage of intestinal contents. The entire mass of the small intestine prolapses; the lower part of the abdomen is seen to be prominent or even patulous, while the upper part is flattened. The liver and kidney become loose and floating. The symptoms are many and distressing. There is general ill health, general depression, asthenia; the patient becomes a chronic invalid, is unable to take exertion, and is only comfortable when recumbent. There is a sense of weight and dragging in the abdomen, pain in the back and continued weariness, burning in the region of the stomach, vomiting, pain, loss of appetite, distress after eating, and more or less dyspepsia. The bowels are irregular, and there is occasionally diarrhea, but as a rule constipation exists. Bowel-

[1] Brit. Med. Jour., Jan. 4, 1896.

movements are productive of pain. Laxatives cause distress, and relief is sought by enemata. The stomach and intestines are usually dilated, and a sense of pressure on the bladder is frequently complained of. The symptoms which we assign to movable kidney are very commonly present. Colic is common, and may be acute. In so-called neurotic subjects these symptoms are greatly intensified, and the condition is engendered which is called neurasthenia. The symptoms are relieved by pressure upon the lower abdomen with the two hands or by wearing a supporting belt. Many patients cannot move about at all until they have adjusted their supports. Physical signs need not be dwelt upon. The liver and the stomach are prolapsed, and return more or less to their normal position when the patient is recumbent. Mr. Treves cites a case of this disease in a young woman in whom he thinks that the course of events was as follows: Tuberculous ulceration of the bowel, followed by tuberculous gland disease, with adhesion of the omentum and gradual dragging upon the stomach and the transvere colon. He says it would be interesting to know if in other instances of Glenard's disease there is an actual causative lesion as in the present instance. This condition of visceral ptosis may be more common than is supposed, because the examinations of the abdominal organs are usually made upon patients in recumbency, and upon patients in recumbency it is difficult to say whether abdominal ptosis exists or not. It would be desirable to ascertain if the mere dropping down of the viscera must of necessity lead to a distressing train of symptoms, or if the patient can have this dropping down and yet have no distressing symptom whatever. We know that some people with movable kidney may be unconscious of it and remain in perfect health. Treves then discusses the question of intestinal neuroses, and reports 2 cases which were purely neurotic cured by abdominal section. In regard to 1 of these patients, who complained of contractions and dilatations of the bowel, Treves mentions the varying condition of the colon when it is placed in front of a large renal tumor. In such cases the colon may be contracted and the condition comparable to a solid growth. It may be dull on percussion, yet before the examination is completed we may find the bowel dilate and give a tympanitic percussion note. Ballooning of the rectum depends upon disturbance in its nerve-apparatus. The dilatation of the gut is not produced by distention with gas; the introduction of the finger or a tube does not cause it to disappear. It may vanish after continued manipulation, and disappears under an anesthetic. It is vaguely associated with some trouble higher up in the canal, usually in the colon, not uncommonly stricture of the colon. It is sometimes very marked in appendicitis and after abdominal operations involving the bowel. Surgery affords many illustrations of that curious transmigration of pain which is common in abdominal troubles and which may play a part in intestinal neuroses. In acute trouble with a small intestine, as, for instance, in strangulated hernia, pain is referred to the root of the superior mesenteric plexus. Renal pain is frequently experienced over the outer side of the hip or thigh and in the heel or sole of the foot. In stone in the kidney the pain may be referred

to the opposite organ. In appendicitis the pain in certain stages may be referred to the opposite side. In one instance pressure upon a diseased appendix during an interval produced pain in the corresponding point of the left iliac fossa. Curious colicky pains in the bowel appear to vanish mysteriously after operations which have rid the patient of some disease of the gall-bladder, kidney, or ovary.

DISEASES OF THE RECTUM AND ANUS.

Allingham[1] considers the question of treatment, operative or palliative, in **carcinoma of the rectum.** During the last 8 years he has seen 720 cases of cancer of the rectum; he has performed excision 62 and colotomy 138 times. He has been led to classify the cases according to the line of action which seems to him proper. In arriving at this classification he bears in mind the following points: 1. The age of the patient; 2. The location and extent of the growth; 3. The nature of the symptoms. Is there obstruction of the bowels? Is there constant diarrhea? Is there hemorrhage, or is there pain? This classification enables him to divide cancers into those cases fitted for excision, those cases fitted for colotomy, and those cases fitted for palliative treatment. If the patient is not over 45 years of age, excision offers very little prospect of permanent success.

The Modern Operative Treatment of Cancer of the Rectum is elaborately reviewed by Gerster,[2] who states that comparatively recent revolution in the methods of surgical treatment of cancer of the rectum is based upon an accidental observation which Volkmann made in 1863. He was removing a periosteal sarcoma and accidentally opened the sacral canal. This accident had long been regarded by surgeons as a very grave one, but Volkmann found that the patient exhibited no serious damage and promptly recovered. Kraske was at this time Volkmann's assistant, and he made a study of sacral injuries, and in 1885 published his conclusions. It is true that in 1874, Kocher removed the coccyx as a preliminary step to removing the rectum, but the importance of this device of Kocher's is not comparable to Kraske's excision of the left half of the lower portion of the sacrum up to the third sacral foramen. Purely anatomic considerations served to encourage surgeons to cultivate this field, and we now see a most remarkable extension of the legitimate indications for surgical interference with rectal neoplasms, but especially a great improvement in the mortality rate, which has descended from the 57% of Iversen to the 20% of Krönlein. The number of colotomies done as a palliative measure has steadily diminished until now it is practically confined to hopeless cases or when internal deposits complicate a removable tumor. We have learned that success very largely depends upon a careful application of asepsis; hence when there is considerable constriction a thorough evacuation of the gut, and hence thorough cleansing, is impossible, and preliminary colotomy is done to enable us to get rid of the fecal matter which is impacted above the stricture. The removal of this fecal mass lessens inflammatory

[1] Lancet, Apr. 25, 1896.

[2] Ann. of Surg., Oct., 1895.

changes, renders the subsequent operation less bloody, and procures freedom from septic fever. Schede and Kammerer think that a preliminary colotomy should be invariably performed. Gerster does not go quite this far. He thinks it is indicated when a satisfactory cleaning of the large gut is rendered impossible or even difficult by whatever cause. The method of colotomy universally advisable is the inguinal one, usually upon the left side. When there is extensive disease with a naturally short mesocolon, it may be necessary to locate the colotomy-wound in the right side of the abdominal walls, as this would not interfere with the bringing down of the stump of the rectum. After extirpation has been successfully accomplished the stump artificially opened is to be closed. Gerster then reviews some of the modifications and improvements of Kraske's plan, and presents all the possible routes of attack upon rectal tumors. The paper itself will be found a very able and yet conservative estimate of the value of these measures.

Andrews[1] strongly disbelieves in the value of **Whitehead's operation for piles,** and writes a paper upon the disastrous results which follow its performance. The peculiar mechanism and important functions of the mucous membrane and submucous tissues of the rectum show that we are not dealing with a simple, smooth mechanical tube, but with a highly specialized organ which cannot be dissected out without doing great or even irreparable mischief? Andrews communicated with a large number of surgeons in Europe and America.

Paul[2] says that **excision of the rectum,** except in minor degree, has not been warmly advocated by surgical writers in England. Even Cripps out of an experience of 400 cases of rectal cancer has only operated upon 38, and appears to disapprove of the major operation. In connection with this subject, Treves does not even mention the name of Kraske or Alexander. Treves thinks that 3 in. is the limit beyond which excision is not advisable, and objects positively to the opening of the peritoneum. Jacobson strongly condemns the high operation, but Paul maintains and argues that the more extensive operations upon the rectum for cancer are in every way more hopeful than those performed for much less advanced disease in the mouth, which almost all surgeons would consider it their duty to perform, and he does not see why they should not equally consider it their duty to do the former operations.

Roux[3] employs the following plan in the **treatment of hemorrhoids:** The patient is placed in the lithotomy-posture and the surgeon's thumbs are carried into the rectum. The rectum is dilated, the thumbs coming in contact with the ischia. A syringe is filled with a 50 to 80% solution of carbolized glycerol, and the fluid is injected into each pile. During the injection the base of the hemorrhoid is held between the surgeon's thumb and index finger. The needle is entered near the anus and pushed through to the base of the pile. This maneuver prevents bleeding. Roux thinks that the dilatation really does more good than the injection.

[1] Mathew's Med. Quart., Oct., 1895. [2] Ibid. [3] Canad. Pract., Dec., 1895.

Morain[1] in speaking of the treatment of **anal pruritus** tells us to seek for the cause and endeavor to remove it. Hot external irrigations are of value, several times a day. Constipation is avoided by taking enemata of oil, and the anus can be rubbed with vaseline. In more obstinate cases he advises that the parts be painted night and morning with a mixture of 60 gr. of alum, 30 of calomel, and 300 of glycerol, or smeared with an ointment containing 60 gr. of calomel, 450 of vaselin, $\frac{1}{20}$ of a part of oleate of cocain, 3 parts of lanoline, 2 parts each of vaseline and olive oil. Another valuable ointment is composed of 60 gr. of red oxid of mercury with 450 of vaseline. Relief is given by inserting a tampon saturated with a 4 in 30 solution of zinc oxid to the anal orifice, or the region may be touched with a 1 in 10 solution of silver nitrate. In very severe cases he uses the galvanocautery or employs scarification.

Van der Willigen[2] considers **ichthyol** as the most valuable drug in the treatment of **anal fissure.** He impregnates a brush with the pure drug, and thus introduces it into the anus, and the contraction of the sphincter muscle forces it into all the folds of the mucous membrane. This treatment is assisted when necessary with castor oil. The results in a number of cases have been most excellent.

Hartmann and Toupet[3] have written an article in La Semaine médicale upon **syphilitic stricture of the rectum.** They state that in stricture of the rectum we find syphilis and tuberculosis very frequently in the history, but that there are many persons who display no evidence of either of these infections. There is usually found marked thickening of the submucous coat, which is transformed into a fibrous mass which may be confused with the mucous membrane and those of the muscular tunic. The mucous membrane is altered, but very rarely ulcerated. Again, in certain parts well-marked tuberculous lesions may be found, and at times well-marked syphilitic lesions may appear, but they are not found in all those who have a specific history. These structures are really inflammatory, and the syphilitic lesion, if it exist at the onset, has only acted in opening the way to infection and in permitting a benign inflammatory process to develop in the rectum. It will be thus seen that in nearly all the cases of stricture of the rectum we are dealing with a stenosing rectitis, and that syphilis and tuberculosis, even if they do exist, which is not always a constant condition, only act by permitting infectious processes to penetrate the mucous membrane.

DISEASES OF THE RESPIRATORY ORGANS.

Pagenstecher[4] presents the subject of **hemothorax,** studied clinically and experimentally, and he has arrived at the conclusion that blood in the pleural sac does not coagulate, because the endothelium of the pleura preserves it as does the endothelium of blood-vessels. Clots do occasionally form,

[1] Rev. Internat. de Méd., July, 1895. [2] Monatsh. f. prakt. Dermat., 1895.
[3] Jour. Cutan. and Genito-urinary Dis., Aug., 1895.
[4] Beiträge z. klin. Chir., xiii. No. 1, 1895.

especially if the pleura itself has been injured, but these clots resemble rather thrombi than ordinary coagula. In case of pneumothorax with healthy pleura the blood will be entirely absorbed in a couple of weeks. If pleurisy arises, it is due to some other factor, as the presence of blood alone will not produce it. As he considers that intrapleural pressure is insufficient to stop bleeding, he does not object to aspiration if it is otherwise indicated. He has but little hope of controlling hemorrhage by opening the chest. [The Société de Chirurgie of Paris debated the subject of pulmonary surgery in November of 1895, and most of the speakers maintained that in wounds of the pleura, when bleeding does not cease spontaneously, the surgeon should enlarge the wound, look for the bleeding vessel, and tie it. In wounds of the chest the surgeon of course determines at once whether the source of bleeding is an intercostal vessel, and if he finds an intercostal vessel to be the source, he resects a rib and ties the vessel. Most surgeons hold that operation is unjustifiable if it seems probable that bleeding has ceased—at least is unjustifiable in such a case unless suppuration occurs, in which condition operation is mandatory. In some cases of hemorrhage a cavity may be packed with iodoform-gauze. Tuffier maintains that a rise of temperature is not a proof of septic infection, and that before operating for supposed sepsis a surgeon should first aspirate and note the nature of the fluid withdrawn. Lucas-Championnière asserts that surgeons are often in too much of a hurry to operate upon cases of hemothorax, as most cases will recover when the side is given rest by immobilization. The Therapeutic Gazette[1] gives a lucid summary of the views which are at present held by many leading surgeons.]

Péan[2] in a recent address upon **the surgery of the lung** gave the results of his own experience, and sets forth the opinions that may reasonably be drawn from a study of the numerous recent papers. He tells us that the surgery of the lung has of late progressed to a great degree because of the advance in anatomic knowledge and the improvement in procedures for the arrest of hemorrhage. The wounds caused by blunt bodies, by sharp instruments, and by small or medium-sized bullets usually heal very well without causing suppuration or grave reaction, the dangers which arise from such injuries being due less to damage of the pulmonary structure than to the number and extent of the wounds and the damage to important neighboring parts. The surgeon must not be in haste to intervene in these injuries, must not be in haste even to make a simple exploration or to attempt to remove a bullet which can be seen near the surface. Large projectiles, such as shell-fragments, give rise to very severe injuries—injuries in which it is usually impossible to save life even by suturing together the two layers of the pleura. A certain number, though but few, spontaneous affections of the lungs are treated successfully by surgical operation. Ordinary abscesses or gangrenous abscesses, when they are limited, when they endanger life, and when they do not progress toward cure by medical treatment, should be treated surgically, and in such cases the results are very generally favorable. When tuberculous

[1] Apr. 15, 1896.

[2] Presse méd., Oct. 23, 1895.

abscesses of the lung cause severe pain, or have established fistulæ, or have taken on widespread pleural adhesions, they should be opened, drained, and even cauterized, and in these cases it is often useful to partially resect one or more of the ribs. The removal of fragments of lung-tissue surrounding tuberculous cavities is perfectly useless, as bacilli have invaded the structure far beyond the apparent disease. In hydatid cysts of the lungs incisions should be practised, and if adhesions do not exist the surgeon should establish adhesions between the parietal and visceral pleura to enable him to wash out the cavity thoroughly. Solid lung-tumors can be removed when superficial, but opportunities to perform these operations will be very infrequent, as lung-tumors are almost invariably secondary. [Injuries of the lung are among the most serious calamities confronting a surgeon. They are highly dangerous, and yet interference seems justifiable only within rather narrow limits. The peculiar structure, the natural activity, and the vital functions of the lung set it as an organ somewhat apart from surgical dogmatizing. Some years ago the extirpation of apices infiltrated with tubercle was looked upon as a promising procedure, but it is now abandoned, and abandoned practically by universal consent. Some few attempts have been made to arrest bleeding from damaged lung. (See Delorme's case.) In most cases the bleeding pulmonary vessel is ligated ; in some instances a cavity is packed with gauze. A foreign body in the pulmonary tissue should in some instances be removed, and an abscess should be evacuated. With the exception of cases of hemorrhage, cases with abscesses, and some cases with foreign bodies in the pulmonary tissue it is questionable if a surgeon should interfere by operation with lesions of the lung.]

Reclus[1] groups the **affections of the lung which demand operative interference** under three heads: 1. Hemorrhage, either traumatic or pathologic; 2. Tumors, such as cancer or tubercle, which demand pneumectomy ; 3. Cavities filled with liquid or with putrid contents, such as tubercular cavities, bronchiectasis, abscesses, hydatid cysts, and gangrenous cavities which are local. Most of the second group of cases require simple incision or pneumectomy. Very few attempts have been made to arrest pulmonary hemorrhage by incision or ligation of the vessel or ligature of the lung itself. Cases have been related, notably by Omboni of Cremona and Delorme, but each patient died. Reclus is of the opinion, when rest, immobilization of the chest, and closure of the wound fail to limit the hemorrhage and death is threatened from syncope, from paralysis of the heart or diaphragm, or from the large amount of the blood in the pleural sac, that the thoracic wall should be incised, the bleeding lung exposed, and either ligatured or packed with iodoform-gauze. It is very rarely that pulmonary tumors can be removed surgically. The first attempt to excise the apex of the lung for tubercle was made by Block. The patient died, the coroner's jury condemned Block severely, and this unfortunate surgeon committed suicide. Since then 6 cases of excision have been placed upon

[1] Rev. de Thérap. Méd.-Chir., Nov. 1, 1895.

record, and of these 2 recovered. Reclus is of the opinion that this proceeding is altogether unjustifiable, because if the lesions are widely diffused the proceeding is too dangerous to be practised, while if it is limited to one apex there is a very fair prospect of cure by ordinary known surgical means. Extirpation for cancer is only justifiable if the tumor passes from the thoracic wall to the adjacent lung and is limited in extent. When the tumor starts in the lung-substance excision is absolutely impracticable, since if the growth is small the diagnosis is uncertain, and if the growth is large operation will be certainly fatal. The surgical treatment of cavities and cysts is more promising. Operation for tubercular cavities is of little use. It is true that there may be some benefit obtained by drainage, yet the original disease is not helped, and sometimes the operation proves fatal; 5% of patients who have been subjected to this operation have died directly from the operation, while 70% have died within 2 weeks and 15% within 4 weeks of it. In only 10% out of 100 reported cases was any real benefit derived, and even in these the disease ran its usual course, unaltered and unchecked. Operation in bronchiectasis has been very disappointing, because there is usually more than one cavity. There may be some improvement from the drainage of the one cavity, but systemic absorption will still take place from the others. Nevertheless, incision is recommended in cases in which dilatation is a prominent phenomena, while sepsis and high temperature are noted and cough and profuse discharge exhaust the patient. Operation for hydatid cyst is of most undoubted value. If these cases are not treated surgically, 54% die; if subjected to simple puncture, 27% die; if treated by incision, only 16% die. Pneumotomy is of very great value in gangrene of the lungs. The mortality after this operation is 25%, while the mortality in cases unoperated upon is 75%. The earlier the operation is done, the better of course is the prognosis, since late operations are done, as a rule, when the patient already has pyemia. Reclus says that the results are apt to be better after 40 years of age, and are worse in women and children than in men. He does not advise operation in every case. It is contraindicated in diffuse gangrene. It is unnecessary in the very limited gangrene in a young person with little constitutional involvement. When the cavity is large, though limited, when it fails to empty itself by cough, and when sepsis is beginning, operation must be done without waiting for serous adhesions to form between the two layers of the pleura. This adhesion makes the task of the surgeon easier, but he cannot afford to wait for its occurrence. In abscesses of the lung, especially in large abscesses of the lower lobe, operation should certainly be performed. Cases not operated on are very apt to die either from sepsis or from asphyxia from the passage of a great amount of pus into the tubes. Men and young people do better after this operation than women and old persons. Pneumonia is a common cause of death. The death-rate in 30 cases was 20%. The author concludes his paper by a presentation of the best operative methods. [The London Practitioner (Jan., 1896) has an excellent abstract of this paper, which abstract we have utilized. In open-

ing cavities Krause uses a thermocautery. This surgeon reports a recent case of gangrene cured by operation.[1]]

Tuffier[2] sets forth a new **method for exploring the lung surgically.** He showed in 1880 how the parietal pleura might be stripped off the thoracic wall in lung-hernia, and he practised the same method in a case of gangrene of the lung. In the latter case the patient was anesthetized and laid upon the left side with a cushion pushed under the flank. An incision in the 8th intercostal space of the right side was made, which incision was 4 inches long; the parietal layer of the pleura being exposed for the whole length of the incision, the lung was seen to move naturally under this outer layer and to look normal in color. The parietal pleura was then stripped from lower border of the 8th rib, from the upper border and from the inner surface, and 2 inches of the 8th rib were excised, and the parietal layer of the pleura was then stripped from the chest-wall over a space equal in size to that of the hand. This enabled Tuffier to explore the lung thoroughly. He found it when squeezed between the fingers to be soft and to be equal in consistency in different places, but in moving upward he discovered a hard portion absolutely different from the rest. Determining this to be the seat of the disease, he removed more of the posterior part of the 8th rib. He was now able to determine that the hard part was of a yellow color, and that the two layers of pleura were adherent above it. He packed the periphery of the wound with iodoform-gauze, incised the hard portion of the lung, and opened into a cavity the size of an orange from which flowed brown pus, clots, and pieces of lung tissue. The cavity was washed out and packed with iodoform-gauze, a piece of gauze was placed in the space between the chest-wall, and the parietal layer of the pleura and the rest of the wound was closed. The patient recovered. [A number of surgeons who debated the subject of pulmonary surgery at the Société de Chirurgie of Paris opposed Tuffier's method of detaching the pleura in operating for deep abscess, thinking that this detachment would be positively dangerous, as pus might gather in the cavity created by the detachment. It seems to us that in operating for abscess the surgeon should observe whether the parietal pleura and the visceral pleura are adherent over the abscess. If these two layers are found adherent, the operation may be at once carried out; but if they are found not to be adherent, they should be made so by stitching with catgut, and the operation should be deferred for several days to permit of union. Thus is pyothorax averted. In operating, the cavity should be found with an aspirator needle; when it is found it is opened with forceps or Paquelin's cautery; it is not irrigated, and it is drained by means of a rubber tube.]

Webb[3] reports a case of **abscess of the lung.** [His case shows the great danger of attempting to inject these cavities. Such an operation as outlined above is far more dangerous than incision; it is liable to be followed by pyothorax, and if bleeding happens an incision will probably be required before we can control it.]

[1] Berl. klin. Woch., 1895, p. 347. [2] Gaz. des Hôp., No. 135, 1895.
[3] Lancet, June 29, 1896.

Parmenter[1] considers the question of **contusion of the lungs** without wound of the walls of the chest and without rib-fracture or rib-dislocation. [The two previous papers show that in some cases it is proper to ligate the bleeding pulmonary vessel on the oozing lung-structure or to pack with gauze.]

Vallas[2] presents a paper on **Transhyoidean Pharyngotomy.** He holds that the pharyngotomy below the hyoid, as usually carried out for the removal of tumors above the epiglottis, has two objections: The transverse cut frequently involves the soft parts to too great an extent, and it also permits the wounding of important organs, especially a branch of the superior laryngeal nerves. [The operation of subhyoid pharyngotomy or of suprathyroid laryngotomy was originally suggested by the celebrated Malgaigne in 1835. This operation has been employed several times for the removal of growths of the epiglottis. An objection to this operation is the limited amount of room the operator is afforded for instrumental work after his incision has been made. This incision might be employed to gain access to a foreign body in the larynx or to an abscess in or near the base of the epiglottis. The elder Gross has told us that the only vessels of importance in this region are the superior laryngeal artery and vein, and they are in no danger of being wounded, as they run along the upper border of the thyroid cartilage. Gross advised that the knife be carried horizontally along the lower border of the hyoid bone.]

Perier[3] mentions 2 patients upon whom he did **laryngotomy without previous tracheotomy.** The operations were for the purpose of removing laryngeal papillomata. He sutured the wound completely. Both cases recovered without bad symptoms. [Laryngotomy has been frequently performed without previous tracheotomy, and Jacobson tells us that some operators even excise the larynx without previous tracheotomy. Treves advises preliminary tracheotomy if much hemorrhage is anticipated. The *Year-Book* for 1896 contains an article of Hislop (p. 336), who describes an extensive cut-throat in which he successfully sewed up the trachea. The paper of Perier and the report of Hislop should suggest whether we should not often seek to close wounds in the trachea and larynx and avoid the insertion of a tube.]

Morgan[4] in a clinical lecture presented a case in which a **foreign body** had been impacted **in the left bronchus** for 46 days, and in which operation was followed by recovery. The patient had been admitted under the care of Dr. Mitchell Bruce with a history that 3 weeks before, while sucking a plum-stone which had cracked, a portion of the stone had been, as was supposed, swallowed. It was decided to attempt to remove the body by operation. The patient was chloroformed, and Mr. Waterhouse made the incision for a low tracheotomy. The trachea was opened; no mucus escaped; a small amount of blood which entered the opening was expelled; the patient was inverted, with vigorous stimulus to the back, but the obstructing body was not loosened. A bent wire with looped extremity was passed down the left bronchus, but did not discover any obstacle. A strand of silver wire with

[1] Buffalo Med. Jour., Oct., 1895.
[2] Gaz. des Hôp., No. 7, 1896.
[3] Bull. l'Acad. de Méd., June 25, 1895.
[4] Lancet, Sept. 28, 1895.

double loop was then passed, and the object was distinctly felt. The laryngeal reflex was excited with a feather. The breathing became spasmodic and violent, but the foreign body was not expelled. A large tracheotomy-tube was then tied in, for which Barker's tube was afterward substituted. About 2 weeks afterward the child was again anesthetized, inversion was tried, and cough was excited by a feather passed down to the trachea. A long probe was then passed down the left bronchus, and a hard substance was felt 5½ in. from the lower margin of the wound. The wound was held widely open by retractors; a pair of forceps was passed down the left bronchus, and the foreign body was successfully withdrawn. This was found to be nearly half of a plum-stone. The wound was left with only a guard wet with carbolic lotion. The patient made an uneventful recovery. The foreign body was apparently lodged at a point where the left bronchus bifurcates into its two main divisions and below the branch which passes to the upper portion of the left lung. [A medical man "stood the patient upon her head." This is a procedure, as Morgan well says, which is never to be carried out unless the physician is ready to do an instant tracheotomy, for instant tracheotomy may become necessary if the foreign body is dislodged. A remarkable feature of this case is that a large portion of the right lung was cut off from normal functional activity for 46 days, and yet the lung apparently sustained no serious damage. Foreign bodies lodge in the right bronchus far more often than in the left bronchus, because the right tube is the larger, and chiefly because the space between the two tubes is toward the left of the middle plane and tends to lead a body toward the right side. The elder Gross recorded a case in which the hull of a bean was drawn into the bronchus; gangrene of the lung began in 2½ months, and the hull was expelled by coughing after many weeks. The chest over the left lung became permanently contracted.]

Cantley[1] in an article upon **the treatment of empyema** shows that empyemata may be absorbed, and this is especially true when they are caused by pneumococci; but to trust in nature is a risky procedure, because rupture may take place through the chest-wall and the presence of pus in the pleural cavity is an absolute indication for operation. The surgeon should endeavor to remove the pus, to prevent any reaccumulation of it, to secure expansion of the lung, and to minimize deformity. Aspiration is only a palliative procedure. The cannula very soon becomes blocked up and some fluid is certain to be left behind. To carry out the fluid with too great rapidity means danger of pulmonary rupture, and hence of pyopneumothorax or of pulmonary edema. Aspiration can be employed in very urgent cases, and in cases of effusion on both sides as a temporary measure, and in cases where the fluid is seropurulent. Some cases do recover under this plan of treatment, but they are few and the risks are considerable.

Cantley prefers incision and drainage to resection of a rib or a portion of a rib. He says that it is very rarely in a child that we are not able to drain thoroughly through the intercostal space—that rib-resection causes more shock

[1] Arch. of Ped., Mar., 1895.

and does not render recovery more speedy. He says that resection in children under the age of 3 shows a vastly greater mortality than does intercostal incision. Another consideration is that opening the medullary cavity of the rib renders the patient liable to pyemia. It is unnecessary to break down adhesions in the cavity, and unnecessary even to explore it. Resection is only employed in those cases in which the ribs are situated in close proximity or as a secondary operation to close a sinus. If drainage is found imperfect after simple incision, resection may then be practised. The tube which we drain with should not be over 2 in. long. A long tube is useless, as we seek cure not by the production of granulations to fill the cavity, but by expansion of the lung, ascent of the diaphragm, and contraction of the side. Since the discharge becomes serous and scanty, the tube ought to be removed, and this may often be done on the third day. To leave it in longer is to keep up continued irritation, which causes the continuance of the discharge. [We are in agreement with the author as to the uselessness of aspiration as a curative procedure, and are not in agreement with him as to the risks of rib-resection. We think he greatly exaggerates the risk of the latter procedure. Resection of a rib or of several ribs may be necessary for drainage, because intercostal drainage is often unsatisfactory, and it may be necessary to permit contraction of the side. In cases where the lung cannot expand we must do the operation of Estländer or that of Schede, although these formidable operations are rarely necessary in children. Wightman's figures in the following paper show that the mortality from simple incision is about equal to that of rib-resection. Rib-resection is of course rarely required in an acute case.]

Wightman[1] considers the **mortality from empyema in childhood.** He maintains that an early diagnosis means a favorable prognosis. The rapidity of convalescence averages from 6 to 8 weeks. If the condition is left alone, it must always prove fatal. Signs of a recent attack of scarlet fever are by no means uncommon in patients who seek relief from empyema at the Children's Hospital. The article on scarlet fever recording 1008 cases, occurring principally in children, which appeared in the Lancet for 1891, has no mention of empyema as a complication. This leads us to infer that empyema is most likely to occur if a case of scarlet fever is neglected. The younger the patient with empyema, the greater the danger of a fatal result. The sooner pus is removed, the quicker the recovery. Rupture through the wall of the chest or rupture through the lung is a very grave complication, though the latter accident occasionally leads to spontaneous cure.

Apart from the danger of rupture, life is chiefly threatened by complications: 1. Pericarditis; 2. Peritonitis; 3. Septicemia. Wightman does not think resection of the rib renders the chance of cure greater or less except in certain cases. At the Hospital for Sick Children, Great Ormond street, from 1880 to 1892, 214 cases were treated; 85 were treated during the earlier period by incision, with 16 deaths, and 129 by rib-resection, with 23 deaths, the mortality being nearly the same in each case. Mr. Godlee in 1886 published the

[1] Lancet, Nov. 30, 1895.

result of 36 cases; 19 were treated by resection, the remainder by incision or aspiration. Only 1 of these cases was fatal. Wightman published, in the Lancet, May 5, 1894, the results of 118 cases, classifying all treatments together. These cases showed 23 deaths. Batten exhibits the results in the Hospital for Sick Children in Great Ormond street for the year 1893–94, showing 43 cases treated by resection, with 5 deaths, and he asserts strongly that resection is the only treatment for empyema; but Wightman maintains that this statement must be accepted with reserve. Cantley in his paper before the London Medical Society in a series of 86 cases treated by various methods showed a mortality of 16.6%, the mortality being the same after resection as after incision, with the exception that 5 out of 6 cases under 2 years old treated by resection were fatal. Cantley's opinion is that resection ought only to be employed in cases in which the tube cannot be inserted without it, when drainage is imperfect, or when we are operating for the cure of an old sinus. Morison had 2 deaths in 34 cases, and maintains that incision is the proper operation. By the courtesy of Mr. Lloyd of Birmingham, Wightman gives the results at the Birmingham Midland Hospital for the last 25 years. There were 123 cases; 99 were cured, 20 died, and 4 were not recorded. There were 43 cases in children of 3 years of age or under, and 18 of these were fatal. In 99 cured cases the average hospital stay was $7\frac{1}{2}$ weeks, the shortest stay being 11 days and the longest 164 days. Resection was performed in only 6 cases. In this hospital the routine treatment is incision and drainage as soon as pus is diagnosed, and resection of the rib is rarely done as a primary procedure. If the above figures are combined, they give 656 cases of empyema in children, with 104 deaths, a death-rate of 16%. The extreme gravity of empyema in young children may be seen by the following table, which considers children 3 years old:

Mortality from Empyema in Children 3 years old and under.

	Cases.	Deaths.
Dr. Goodhart (Guy's Hospital Reports)	29	19
Birmingham Children's Hospital	43	18
Liverpool Children's Hospital	36	18

These figures give a death-rate of a little over 50%.

Marshall[1] was induced by Wightman's paper, which we have previously noted, to collect the cases of empyema which had been under his own care since May, 1879. All his cases were treated by free incision with the exception of 2, where, owing to the grave condition of the child and the extent of effusion, it was deemed best to relieve the chest by a limited aspiration some hours before free incision. Marshall thinks this precaution is very useful. Marshall had 45 cases with 7 deaths. Only 7 of these cases were under 3 years of age, and of these 2 died. The method of treatment may be summarized as follows: 1. Free incision; 2. A single tube in infants, but a double-barrel tube in all above the 3d year; 3. The complete emptying of the chest

[1] Lancet, Dec. 21, 1895.

of fluid for the first week after operation by turning the child on the side, as one would empty a barrel, twice every day. This emptying is assisted by efforts at coughing if the child is old enough to understand; 4. The removal of the tube at the end of the first week; 5. Allowing the patient to sit up and move about as soon after the first week as possible, thus helping the expansion of the lungs.

The writer has never found it necessary to resect a portion of the rib in an acute case. The following facts were of interest in connection with the deaths: with 1 exception every fatal case was on the left side. This fact confirms the belief that left-sided pleuropneumonia is more dangerous than the right-sided variety. In every death there was a history of long illness before admission—illness for from 6 weeks to 3 months. In 1 case gangrene of the lung was supposed to exist, but postmortem did not disclose it. Of the 2 deaths occurring in children under 2 years of age, 1 was due to chicken-pox, and in both the children were very rhachitic. One case suffered from thrombosis of the left iliac vein 6 days after operation, and died on the 8th day. Marshall concludes that free incision when performed early is a very successful operation; that rib-resection is never required in an acute case; that death at any age is rather the result of neglect to recognize the true nature of the case than it is of the operation itself. [Blowing systematically in a washbottle is a great aid to lung-expansion if a child has reached an age when he can be made to carry it out.]

Fulton[1] advises the use of **the curet in operations for empyema,** because he has found that a certain number of cases in which resection of rib followed by drainage has been done do not go on to complete recovery, but require other operative measures or else terminate fatally. The question is how to reduce the already small percentage of failures from operation, and the writer thinks the cause of failure is often due to incompleteness in operation. We may find any one of two or three different conditions present. We may find only pus in the pleural cavity; we may find also large masses of coagulable lymph. We may find also that the pleural surfaces are covered with a deposit of lymph even to the thickness of several lines. In the first of these conditions drainage will bring about cure; in the second the coagula must be removed with a scoop or a finger if drainage is to effect a cure; in the third the lymph upon the pleural surfaces must be removed by means of a curet. After resection, douche the cavity with hot water; the entire cavity is then gone over with a curet, the douche being kept going all the time. The pleura must not be wounded, and in order to reach the entire surface curets must be used which have flexible handles. After the entire cavity has been curetted and irrigated it is dried and packed, and the treatment from that time is the same as if we were dealing with a large abscess anywhere. [The fallacy in this plan is that the treatment is based upon the assumption that we wish to obtain granulations as in an ordinary abscess. We do not wish to obtain anything of the sort. Filling of the cavity is not brought about by granulation,

[1] Med. Rec., Nov. 2, 1895.

and is brought about by expansion of the lung, elevation of the diaphragm, and contraction of the chest-wall. Irrigation of the pleural sac has been proved by ample experience to be dangerous. Curetting the pleura is, in the first place, useless, and is, in the second place, more dangerous than irrigation.]

Gamgee [1] discusses the details of 25 **tracheotomies** in children under 2 years of age; 21 of this number were operated upon for membranous croup or diphtheria, and 11 were cured. Of 8 patients of 2 years of age or under, there was 1 recovery. This was in a patient who had a scald of the larynx. There were 16 operations on children of more than 2 years of age, with only 3 deaths. Gamgee quotes from the statistics of Fischer of Hanover, covering the period of January, 1894, to September, 1895, in which there were admitted into the Hanover Hospital 1510 cases of diphtheria, and tracheotomy was done upon 1000 of these. In 1885 there was no epidemic of diphtheria, and in this year there were 48% of recoveries. In 1886 and 1887 there was a bad epidemic of scarlet fever, and there were only 27% of recoveries. These figures show that the results of tracheotomy and diphtheria depend largely upon the type of the disease, and that the mortality is always higher when an epidemic of scarlet fever or of diphtheria exists. Two other facts influence the mortality of the operation: first, the presence or absence of pneumonia, and second, the severity or mildness of the asphyxia. The indications for operation are retraction of the cartilages, a progressive increase of the symptoms despite medical treatment. Chloroform should be given except when the child is semi-conscious and cyanosed. The general rule of operation is that the isthmus of the thyroid gland is drawn downward, the deep cervical fascia is cut transversely, and the trachea is incised above the isthmus. If we are dealing with a child who has a short neck, we need never hesitate to cut the isthmus. The bleeding is slight, the method gives a good exposure and saves much time. Unless the case is urgent, the trachea ought not to be opened until bleeding has ceased. The tube employed should be a bivalve, should have a movable shield, and should be as large a size as possible. The operator must be very careful not to strip up the fascia in front of the trachea, as emphysema of the mediastinum may result over the entrance of air beneath this fascia. After operation the patient should be placed in a tent near the fire, but we should use no steam kettle, as the moist atmosphere weakens the patient and does not benefit him. Considerable amounts of food should be given by the mouth unless fluids are regurgitated through the trachea-tube, and in these cases we must feed by a nasal tube. At the end of a week we can begin to make attempts to leave out the tube. This is done gradually, so that the child regains the capacity to breathe through the larynx; in some few cases the tube must be worn for a longer period of time, even for life. One of the most difficult things to overcome when the child again attempts natural breathing is fright. This fright produces spasm of the larynx. We can overcome this by using a tube with an opening on its convex surface, which opening can be plugged for a few minutes at a time now and then. In some cases granulations form at the

[1] Birmingh. Med. Rev., Mar., 1895.

tracheolaryngeal junction. A well-fitting tube which is dispensed with soon prevents this complication. If granulations do form, they must be touched with nitrate of silver. [In urgent cases we can open the trachea even before hemorrhage has ceased. This can be done with entire safety if the patient is recumbent with the head lowered. The hemorrhage is largely venous, and the venous channels are distended because of asphyxia. The opening of the windpipe relieves asphyxia, and hence the venous distention, and the relief of venous distention leads to the arrest of hemorrhage.]

Warren[1] presents an interesting case of **cervical rib** which was removed by operation. The patient was a woman 35 years of age who for years had had pain about the shoulder, which she supposed was rheumatic. During the last 2 or 3 years the pain became much aggravated; it was felt chiefly about the middle of the right clavicle and extended down the arm, sometimes all the way to the lower end of the ulna. Of late the power of the arm seemed to have diminished. A bony tumor was found behind the middle of the right clavicle, which tumor appeared to arise from the first rib. A large artery was found overlying the tumor. The outer border of the tumor was found to be very sensitive. A much smaller bony prominence, but one entirely similar, was found on the opposite side of the neck. Warren uncovered the whole region of the tumor by making a large rectangular flap. He incised the fascia and exposed a bony mass which lay upon the inside of the subclavian artery and on the outside of the brachial plexus. This mass was found to be a rib articulating with the first rib by a facet situated a short distance behind the insertion of the scalenus anticus. The scalenus medius was inserted into the cervical rib. This rib was disarticulated and removed piecemeal, nearly up to its point of origin from the 7th cervical vertebra. Removal of the bones seemed to relax the brachial plexus, which had been somewhat stretched. The patient made an excellent recovery, has had no pain since, and has recovered the use of the arm. Warren reviews the literature of the subject, and quotes especially the paper of Ehrlich and the paper of Tilmanns. [Cervical ribs lead to great errors of diagnosis. In some cases the pulsation of the subclavian artery over a cervical rib has led to the view that an aneurysm existed. Some of these ribs are short; some of them are long, joining the first rib or first costal cartilage; some are immovable and some are movable. They rarely cause symptoms. T. de Quervain[2] has recently put another case upon record which he operated upon and removed.]

DISEASES OF THE VASCULAR SYSTEM.

Delorme and Mignon[3] have devised a method for **puncture and incision of the pericardium** which they think far safer than that formerly employed. The operation for puncturing the pericardial sac is as follows: A very small skin-cut is made in the 5th left interspace, close to the sternal margin, and an aspirating needle is introduced closely against the bone. The needle is

[1] Boston M. and S. Jour., Mar. 12, 1896. [2] Centralbl. f. Chir., No. 407, 1895.
[3] Gaz. des Hôp., No. 149, 1895.

kept first by the sternal edge, and then by the posterior surface of the sternum for a centimeter, and is then pushed directly downward and a little backward to a depth of several centimeters until liquid appears in the aspirator. To practise incision of the pericardium the surgeon finds the edge of the left pleura and pushes it outward. Two centimeters of the 5th and 6th cartilages are excised by means of gouge forceps, commencing at the edge of the sternum. The intercostal vessels of these spaces and the triangularis sterni are then pushed away with the fingers. The pericardium is distinctly visible at the bottom of the wound, being of a pearly-white color.

[In regard to the pericardium it is interesting to note that Dalton sutured a stab-wound in the pericardium, and the patient recovered. 5 in. of the 4th rib was resected, the intercostal artery was ligated, the pleura was cleansed of blood and clots. The incision in the pericardium was 2 in. long, and was closed with a continuous catgut suture.]

Ferguson[1] suggests a method of operation upon **varices of the leg** (Fig. 61). He thinks that Madelung's method, which consists of cutting down immediately over the varices and resecting them in part, has the difficulty of encountering the body of the veins at their pathological points, and the disadvantage of not getting at the branches. The operation is not sufficiently radical, and return is liable to recur in the diseased veins left unremoved. The method of Phelps, which consists in cutting down over the varices and applying multiple ligatures, makes too many punctures and does not get completely at all the venous branches. Schede made a circular incision around the leg, rolled one cuff up and another cuff down, with the idea of reaching the different venous branches and removing them. But we can only reach a limited amount of the varices with the circular incision. A circular incision below the knee cannot expose the veins above or behind it, and vice versa.

FIG. 61.—Ferguson's incisions for varicose veins (Chicago Med. Recorder, June, 1896).

Ferguson's method is as follows: The saphenous vein is tied in two places near the femoral, above its abnormal area, and a section of the vein is removed. The object of doing this part of the operation first is to allow all the varices to show. A semilunar incision is now made through healthy skin, and is extended as far down as it is necessary to go until we partly surround all of the varices. It is then deepened through the superficial fascia and fat down to the fascia lata. In the line of this incision we cut off all the venous supply. When the incision is completely down to the deep fascia, the entire flap is raised and dissected up. The veins normal

[1] Chicago Med. Recorder, June, 1896.

and pathologic are raised with the flap, and the varices and their branches are dissected away from its under surface. In raising the flaps the venous communications with the deep veins are severed and ligatured.

This method also exposes varices of the short saphenous. Ferguson has used this method for over 3 years. He sometimes uses 2 semilunar incisions instead of 1 when the varices are far apart and the intervening veins are normal. [Trendelenburg advised ligation of the long saphenous vein below the saphenous opening. All the above operations seek cure by lessening the amount of the column of blood. An apparatus has been advised to accomplish this, a sort of truss which has been highly praised as obviating the necessity for operation. (See *Year-Book* for 1896.)]

Patrick J. Hayes[1] suggests a modification of the **distal ligature for aneurysmal dilatation.** Every now and then the surgeon is confronted with cases where it is impossible to deal with the proximal portion of the diseased artery, and where he must consider the problem of inducing coagulation within the sac either by distal ligation or the extremely hazardous method of introducing foreign agents through the sac-wall. After these operations of ligation there is occasionally observed a prolonged delay before there is any evidence of improvement, and in the thin-walled aneurysm such retardation may entail rupture of the wall, when otherwise cure would have been the result of operation. Hayes advises a method which he thinks will rapidly secure the formation of a thrombus extending from the distal point quickly and safely.

The surgeon exposes the arterial trunk, and passes two ligatures beneath it with a $\frac{1}{2}$ in. of distance between them. The distal ligature is at once tied. The proximal ligature is loosely tied with a single knot which just serves to very moderately compress the arterial walls. A small incision is made in the artery midway between the ligatures, and through this incision a slender cannula carrying a piece of catgut is introduced and directed toward the proximal portion of the vessel. The gut is pushed on through the cannula until its end has reached or entered the aneurysm. The cannula is then withdrawn and the proximal ligature is firmly tied. The artery and the free part of the catgut are now cut across at the site of aperture between the ligatures. This foreign substance introduced into the sac soon becomes enveloped in a coat of fibrin, and, as it were, acts as a gubernaculum for the extension of the coagulating process. At the same time we have not injured the sac-wall by any needle-puncture, while the risk of distant embolism has been guarded against by the previous distal ligation.

W. S. Kerr[2] of the Sheffield Infirmary reports an interesting case in which a large-sized **iliofemoral aneurysm was cured by compression** of the abdominal aorta. The patient was anesthetized, and Lister's abdominal tourniquet was applied a little below and to the left of the umbilicus. It was found that by moving the tourniquet a little lower and a little more to the left the pressure was determined toward the left common iliac artery, which

[1] Lancet, Oct. 12, 1895.

[2] Quart. Med. Jour., Oct., 1895.

allowed the circulation in the right limb to become reestablished and relieved the cyanosis there. The anesthetic was continued for 7 hours. After the pressure had been on $5\frac{1}{4}$ hours the tumor appeared to be quite solid, and the tourniquet was slowly relaxed at the rate of a quarter turn a minute. After a few turns of the screw the cyanosis in the left limb began to disappear, and 7 hours after the beginning of the procedure the tourniquet, being quite loose, was removed. The aneurysm was found solid without a trace of pulsation or bruit, and no pulse could be detected in the left femoral, popliteal, or posterior tibial arteries.

The progress of the case was one of gradual recovery as far as the tumor and the general health of the patient were concerned, although on the 4th day the toes of the left foot became gangrenous and soon separated.

Hufschmid[1] reports a successful **ligation of an aneurysm of the vertebral artery.** Compression of the common carotid artery was found to control the pulsation in the large bloodvessels which overlay the tumors, but not of the tumor itself. An incision almost 3 in. long was made over the level of the thyroid cartilage along the posterior margin of the sternocleidomastoid muscle and then deviating to a distance of a finger's breadth from this muscle. The incision reached the supraclavicular fossa. The clavicular portion of the sternomastoid was divided a little more than an inch above the clavicle. The muscle was sewed with catgut, the wound was closed with silk and silver and was drained with iodoform-gauze. There was complete cure.

Herbert L. Burrell[2] reports a case of **ligature of the innominate artery** in which the patient lived 104 days, and died finally, not from the result of operation, but because of the general congestion of Bright's disease. Burrell appends a table with all of the reported cases.

Brigade-surgeon-lieutenant-colonel W. F. Stevenson and Surgeon-major H. J. Michael[3] report a case of **transperitoneal ligature of the common iliac artery** for diffuse traumatic aneurysm of the external iliac and common femoral arteries. The operation was divided into two stages. They first ligated the common iliac by the transperitoneal method, and at a later period made an incision over the tumor in the line of the sartorius muscle, turned out $2\frac{1}{2}$ lb. of soft blood-clot, and packed the cavity with iodoform-gauze. There was little or no hemorrhage.

Souchon[4] of New Orleans reports the case of a man with **two aneurysms** of the left thigh, one in Scarpa's triangle as large as an egg, and the other at the adductor opening as large as a cocoanut. The superficial femoral was ligated after compression had failed to cure. The surgeon ligated the artery in the middle of Scarpa's triangle, and used a double continuous kangaroo ligature, so as not to rupture the coats of the vessel. This required tying the bleeding upper end of the vessel with silk. Pulsation ceased in the aneurysm by the adductor opening, but returned in the upper aneurysm. Hemorrhage occurred again, and both ends had to be tied. The patient was

[1] Arch. f. klin. Chir., 1896, B. lii. H. 1, p. 23.
[2] Boston M. and S. Jour., Aug. 8, 1895.
[3] Lancet, Jan. 25, 1896.
[4] N. Y. Med. Jour., Nov. 2, 1895.

ill for a long time, and during this time the lower sac was opened and the clots were turned out, and the upper wound was opened and a silk ligature remained. The patient finally recovered.

The author thinks that previous application of compression complicated the case. In high femoral aneurysms he thinks it would be well to apply a provisional ligature to the artery. He thinks it would have been better to have extirpated the upper aneurysm rather than to have ligated, and this would have cured both aneurysms at once.

W. Thelwall Thomas[1] of Liverpool reports a case of **cut-throat** in which all the carotid arteries and all the jugular veins on one side were ligatured, and in which the patient was given intravenous saline transfusion and finally recovered. The sternomastoid and omohyoid muscles were cut; the internal jugular vein was cut through; its cut ends were collapsed and three-fourths of an inch apart. The common carotid artery was cut into, but not divided. The thyroid cartilage was notched, and the external and anterior jugular veins were severed. The following treatment was pursued: Ligature of the common carotid in two places (3 and 4, Fig. 62); ligature of the internal jugular in two places (1 and 2, Fig. 62); ligature of external and anterior jugular; perfusion of 20 oz. of saline fluid. Twenty-two days later secondary hemorrhage occurred, and an attempt was made to ligature the common carotid (5, Fig. 62). Ligature of internal jugular and branch (6 and 7, Fig. 62) was performed by Mr. Bickersteth. In 9 days more there was another hemorrhage from the internal carotid, which was treated by packing and pressure and the injection of 2 pints of warm water by the rectum. The patient subsequently recovered.

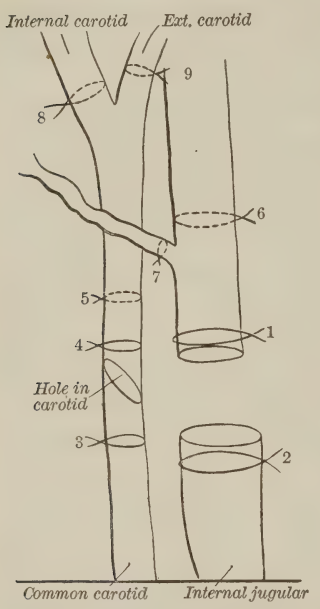

FIG. 62.—Ligatures applied in Thelwall Thomas's case of cut-throat (Brit. Med. Jour., Dec. 7, 1895).

Ricard[2] reported to the Ninth French Surgical Congress 2 cases in which he had successfully **sutured large veins.** In the first case he sutured the brachiocephalic vein with a Lembert suture, and supported the vein by suturing the tissues carefully about it as well. In the other case he sewed up an incision in the femoral vein with four stitches, just as in the ordinary wound, and then stitched the soft parts above it. Both cases got perfectly well without hemorrhage or subsequent circulatory disturbance, so that the inference is just that the lumen of the vessel was left free.

Glück[3] of Berlin says that in many cases **wounds of veins** have been successfully sutured. He says that Zoege-Manteuffel in extirpating an arterio-

[1] Brit. Med. Jour., Dec. 7, 1895. [2] La Presse méd., Nov. 6, 1895.
[3] Berl. klin. Woch., Aug. 26, 1895.

venous aneurysm of Scarpa's triangle ligated the deep femoral artery, closed a wound in the femoral vein by lateral sutures, and then, having wounded the common femoral artery, sutured that vessel also, the patient recovering without gangrene. He says that Israel successfully sutured the common iliac.

Heidenhain[1] reports a successful case of **arterial suture.** He was operating on a carcinoma of the breast, and an assistant wounded the axillary artery while using the scissors. The wound was longitudinal. The edges of the wound were picked up with forceps, and the wound was sutured with a fine catgut suture inserted with a round intestinal needle. The suture scarcely narrowed the vessel's caliber. It was found necessary in this case, because of the extensive nature of the disease, to remove a portion of the axillary vein. The pulsations of the artery continued, and 6 months afterward the patient was in excellent condition.

Heidenhain does not approve of inverting the walls and sewing only the adventitia and media, but he believes in bringing the endothelial surfaces in contact by approximating the surfaces of the intima. [Ricard successfully sutured a tear in the innominate vein.]

W. A. F. Bateman[2] of the Richmond Royal Hospital reports a case in which operation was performed for **cancer of the head of the pancreas,** and in which transfusion was rendered necessary by the exhausted condition of the patient during operation. He used for transfusion defibrinated sheep's blood from a recently selected animal. The blood was mixed with an equal quantity of water in which was dissolved table salt in the proportion of a dram to a pint, and the mixture was carefully strained through fine muslin. The temperature of the fluid when injected was 98° F. He used to inject with a common Higginson's enema apparatus to which was attached an aspirator needle. He injected not quite 8 oz. He considers that the injection greatly improved the condition of the patient. He thinks that the method is worthy of a further trial—first, to determine whether the material is as valuable as human blood; second, because there are obvious advantages in its use. It is easy to obtain, and we are free from the danger of injuring a person by abstracting blood.

Gottschalk[3] advocates the use of stypticin as a hemostatic. Stypticin is an agent which is obtained by oxidation of narcotin. It may be given hypodermically or may be administered by the mouth. Three-fourths of a grain administered five or six times a day will produce no evil effect. One great advantage is that it is not only hemostatic, but it is strongly sedative both locally and generally.

C. Hamilton Whiteford[4] has been much struck by the **profuse hemorrhage** which occurs during **Estlander's operation.** In order to lessen this hemorrhage he advises the following method: After exposure of the thoracic wall the intercostal arteries are compressed by ligatures on each side of the pieces of rib to be removed. An aneurysm needle is passed unthreaded from the middle of one intercostal space, entering the pleural cavity, to the

[1] Centralbl. f. Chir., 1895, p. 1113.
[2] Brit. Med. Jour., Jan. 4, 1896.
[3] Ibid., 1896, No. 1828, p. 7.
[4] Lancet, Mar. 7, 1896.

space above, and brought out close to the upper border of the rib above. The needle is then threaded and withdrawn, and this ligature when tied contains below the rib a bundle of intercostal muscle which plugs the intercostal groove. The entire thickness of the chest-wall is removed between two rows of these ligatures and close up to them, the bleeding being confined to the divided ribs. Where time is no object the periosteal flaps to cover in the cut ends of the rib tend to prevent subsequent necrosis, probably by preventing the infection of the bone by pus from within. The ligature should consist of some absorbable material. [If we resect rib after rib, removing each as if we were doing a separate operation, we can easily push the periosteum off of the rib and carry with the periosteum the intercostal artery. The artery is tied before the lower layer of periosteum is incised and before the pleura is cut. We find that this method greatly limits hemorrhage.]

John McMullen[1] considers the value of the **Esmarch bandage in hemorrhage and shock.** One does not always have a transfusion apparatus convenient. It is true that axillary injection is very valuable, but absorption from the subcutaneous tissues is slow in shock. For this reason he mentions a treatment not in general use. He takes an Esmarch bandage, wraps all the the limbs firmly, beginning at the distal end, thus driving all the blood into the body, stimulating the heart and giving it less to do. If he does not have an Esmarch bandage, he uses an ordinary bandage and applies a tourniquet over the main artery. This is of great value in burn cases in children and in postpartum hemorrhage, and in some cases of heart-failure. It is especially useful in case of threatened death from chloroform. [This is the old method of autotransfusion, devised, we believe, by Hunter, although McMullen employs a rubber bandage instead of a muslin one. The method is often employed in the Philadelphia hospitals.]

McNeill[2] of Australia maintains that voluminous **intestinal enemata of hot saline solution** are of great value in cases of hemorrhage. The tube must be carried through the sigmoid flexure, and the injection must be forced until it causes decided tension, because the greater the tension the greater the absorption.

Whitelaw[3] of Edinburgh places on record some interesting observations in regard to **hemorrhage,** and he considers that hemorrhages are predisposed to by an abnormally high barometric pressure.

A. E. Hind[4] reports a case of **hemorrhage from the extraction of a tooth** in which pressure and plugging had failed to arrest the hemorrhage. It was instantly arrested by freezing with ethylchlorid spray after clearing out the clots. To prevent recurrence on thawing, wool soaked in tincture of hamamelis was applied. [In a recent case seen by one of the editors (DaCosta) with Dr. Wylie of Philadelphia the cavity was frozen with ethylchlorid, and was packed with gauze wet with a 10% solution of antipyrin. A roll of gauze was placed over the plug of gauze, and this roll forced the jaws apart. A

[1] Brit. Med. Jour., Mar. 14, 1896.
[2] Australian M. Gaz., Dec. 20, 1895.
[3] Brit. Med. Jour., May 30, 1896.
[4] Lancet, Jan. 25, 1896.

Barton's bandage was firmly applied so as to make continued pressure. Bleeding was at once arrested and did not recur. The plugs were removed in 48 hours, a light packing was inserted in the tooth-cavity, and the bandage was not reapplied.]

"The Treatment of Excessive Hemorrhage" is the title of an article by Charles Jennings.[1] He considers the relative merits of various plans of treatment. There is no question that the injection of saline fluid into the

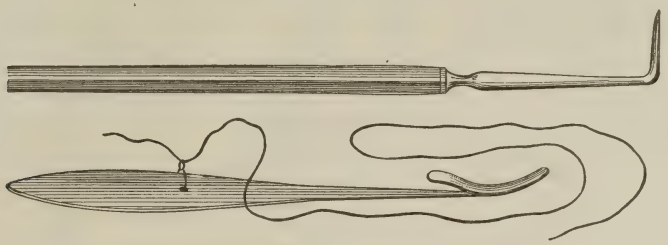

FIG. 63.—Jennings' instruments for exposing and tying the vein (Brit. Med. Jour., Feb. 8, 1896).

subcutaneous cellular tissue is one of the methods by which the effect of otherwise fatal hemorrhages may be counteracted, but absorption of fluid from the cellular space is tardy. It may take 2 hours before there are indications of

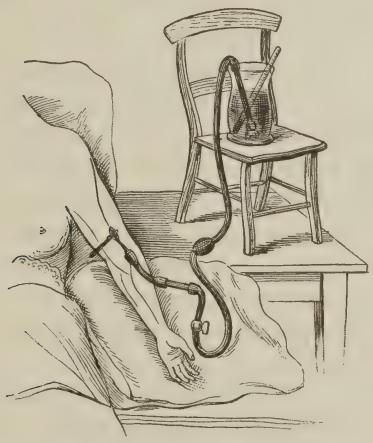

FIG. 64.—Transfusion of saline fluid (Jennings, in Brit. Med. Jour., Feb. 8, 1896).

improvement, whereas when we inject into a vein benefit is instantaneous. Jennings presents the instruments for intravenous injection and for transfusion which he invented, and which enable us to rapidly perform the operation. The accompanying illustrations (Figs. 63–65) render clear this method.

[If saline fluid is thrown into the connective tissue, absorption is greatly accelerated by employing toward the heart after the plan of Münchmeyer. The custom of leaving several pints of saline solution in the abdomen after a laparotomy has been approved by many surgeons. (See Treatment of Hemorrhage by Infusion of Normal Saline Solution, John H. Glenn, in Dublin

[1] Brit. Med. Jour., Feb. 8, 1896.

Jour. of Med. Sci., Sept., 1895.) Ponfick has employed direct injection into the abdominal cavity. The rectum will often absorb when the stomach will not; hence rectal injection of normal salt-solution is a valuable expedient. It is a routine custom in the Johns Hopkins Hospital to give such an injection

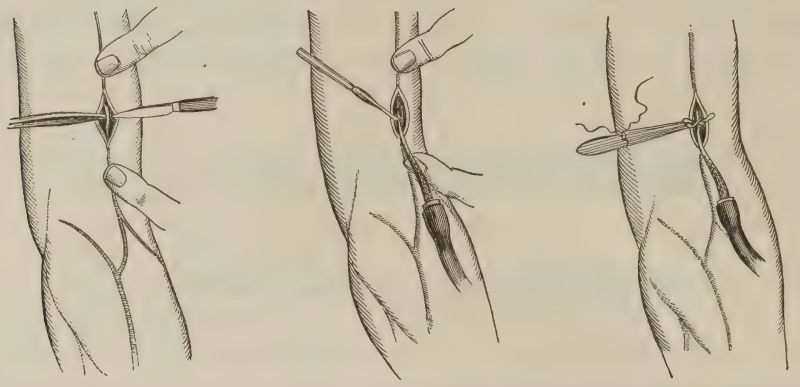

FIG. 65.—Exposure of vein and insertion of cannula (Jennings, in Brit. Med. Jour., Feb. 8, 1896).

before the patient is taken from the operating table. It prevents thirst and hemorrhage, and reacts the patient from shock. The best method in severe cases is by intravenous injection. Glenn thinks that intraarterial injection has a promising future (see Collin's apparatus, p. 224).]

Mr. Thomas Bryant, the distinguished surgeon of Guy's Hospital, has a valuable article in the Lancet, May 9, 1896, upon **obstructed arteries,** and he reports many interesting cases: one case of aneurysm of the aorta, giving rise to laryngeal symptoms, apnea, and sudden death, in which there was almost complete closure of the orifice of the left subclavian artery; another case, of aneurysm of the aorta and innominate artery, in which ligature of the right common carotid was undertaken; death occurred on the 14th day. There was obliteration of the origin of the left subclavian. He then considers laceration of the inner coat of the aorta with fracture of the spine and laceration of the jejunum; a case of contusion of the arm with occlusion of the brachial artery; a case of lacerated and obstructed axillary artery in a boy aged 8 years; a case of separation of the lower epiphysis of the humerus from the diaphysis and displacement of the epiphysis of the bones of the forearm backward, with occlusion of the brachial artery; a case of compound fracture of the humerus, with occlusion of the brachial artery; a case of compound fracture of the humerus into the elbow-joint, with occlusion of the brachial artery; a case of contusion and occlusion of the external iliac and common femoral arteries; a case of ruptured popliteal artery, occluded artery; fractured pelvis with obstruction of the external or common iliac artery; fracture of the pelvis, occlusion of the external iliac artery, gangrene of the foot and leg; fractured pelvis through the thyroid foramen, occlusion of the iliac artery, rupture of the urethra, and partial rupture of the bladder. The ultimate consequences depend on treatment. A limb suddenly deprived of its arterial blood-supply is more

apt to become gangrenous than when the deprivation has been gradual. This tendency to gangrene is due primarily to the sudden deprivation of the tissues of nutriment, and secondarily to the blood-stasis which follows the accident, either because of simultaneous injury of the accompanying veins or from the loss of normal vis a tergo. The object of the surgeon is to encourage in all ways the arterial as well as the venous circulation, and to guard against blood-stasis. We should place the limb, if it be the lower extremity, upon a splint to keep it quiet, after it has been carefully rubbed upward and gently kneaded to encourage the flow of venous blood through the muscles and deeper parts. This splint, with the limb upon it, is raised sufficiently, but not more than sufficiently, to help the return of venous blood to the heart, but not enough to interfere with the supply of arterial blood through the new arterial channels which have to undergo compensatory enlargement. Hence the foot should not be more than 1 or 2 in. higher than the knee, nor should the knee be more than 1 or 2 in. higher than the hip. The limb is cold and requires warmth, but to apply too much warmth or to apply it too suddenly will do harm, for an excess of warm blood would then be thrown into the part, and, as the power of the tissues to pass blood on is largely lost, stasis will inevitably result. Warmth should be applied cautiously, and not until the venous circulation has been helped by gentle upward rubbing and by kneading of the deeper tissues with a warm hand below the seat of injury. Subsequently the limb should be wrapped in cotton wool and gentle pressure should be applied by means of a flannel bandage. In the general treatment of the case we should avoid overstimulation, and simple nutritious food should be given. Wine and spirits must be administered with great caution. Should gangrene follow, amputation will be necessary, but it should not be performed until indication is afforded of the extent to which it is likely to spread—until, in fact, a line of demarcation can be made out—and then amputation should be performed above this line in healthy tissues. We need not perform the amputation far from the line, as we do in senile gangrene, for in senile gangrene the vessels of the limb are known to be diseased, whereas in the injuries we are discussing they are probably sound, except at the seat of injury. If septic changes take place in the limb, surgical interference must be hastened, but if the limb has been rightly treated and well raised, the probabilities are that only dry gangrene will occur; whereas if the limb has become swollen and edematous, septic changes are sure to show themselves. In dry gangrene delay is to be sanctioned. In the moist form surgical interference will be called for at an early period, and must be carried out under unfavorable circumstances. In treating fractures complicated with obstructed arteries, in most cases the surgeon should assume the attitude of expectancy, for in most cases of this kind the limb is sufficiently well nourished to undergo repair. It is only in exceptional cases that gangrene follows and amputation is demanded.

Bryant concludes his paper by quoting 7 cases, in each of which at some antecedent period a large artery had been obstructed, and recovery followed. The cases came before him for some independent surgical operation.

DISEASES OF THE LYMPHATIC SYSTEM.

J. Schwinn[1] of Wheeling, W. Va., reports a case of **injury to the thoracic duct** during an operation at the root of the neck. He was operating for a mass of tubercular glands on the left side of the neck, and during the entire operation there was no indication of anything going wrong, and the wound healed its whole length by first intention, but on the 10th day after operation a swelling appeared over the left sternoclavicular region. There was no fever and no pain. Two days later the swelling was notably larger and fluctuated. The lower angle of the incision was opened with a probe, and there gushed forth a liquid looking like skimmed milk, and proving under the microscope to be chyle. About 1½ oz. were obtained. Exploration disclosed a cavity containing 2 oz. more, and this cavity was packed with iodoform-gauze. The packing made matters worse, and the quantity of chyle discharged during the 24 hours after the packing amounted to nearly 2 pt. This heavy loss of nutrient material affected the health of the patient. He lost flesh, grew weak, and had severe attacks of syncope. He suffered with most intense thirst, and whenever fluids were given him to relieve this thirst there was an increased flow of the chyle. The patient was taken back to the hospital, the original incision was opened, and the leaking point was found in the form of a small vessel torn through, the free opening being the size of a knitting needle. This vessel was so situated that ligation would have been difficult; Schwinn therefore put a clamp on and packed the cavity around this with gauze. The clamp came off on the 3d day and the patient made a complete recovery.

This case differs from all other reported cases of injury of the thoracic duct in the fact that the flow of chyle did not begin during or soon after the operation, and, further, in the fact that the gauze tampon made the flow worse. This occurrence may be explained in the following way: There was a tear of one of the large branches of the thoracic duct. During and shortly after the operation, the walls of this torn vessel being curled in, the escape of chyle was prevented. But when the vis a tergo from the main duct came into play the obstacle was removed and there was a slight flow, corresponding to the size of the vessel, pressure resting on it from the overlying skin and dressing. As soon as the gauze tampon was introduced right to the open mouth of the torn vessel the chyle was drained away from the main duct in much larger quantities, so as to leave the impression that the main duct itself had been wounded.

The author advises that when we enucleate glands through the base of the neck we should always put a ligature around their lymph-vessels. [The ligature of the lymph-vessel is usually impossible, but it cannot be seen.]

Mr. D'Arcy Power[2] presents remarks on **cystic lymphangioma** in childhood, and makes report of a case. These growths may occur in any part of the body. They are not unusual in the neighborhood of the axilla. They are less frequently met with on the face, but they are seen in the tongue, where they cause macroglossia, and even in the mucous membranes of the intestines. A cystic lymphangioma varies from a few scattered cutaneous vesicles filled

[1] Ann. of Surg., May, 1896.

[2] Brit. Med. Jour., May 16, 1896.

with lymph to a tumor of great size. The scattered vesicles, to which the fanciful name of lupus lymphaticus and the more correct name of lymphangioma cutis circumscriptum has been given, will not be mistaken for anything else. But the more solid forms of tumors must be distinguished from enlarged lymph-glands, from fat tumors, from nevus or other form of blood-cyst, from the dermoid cyst, and from the sarcoma, for any one of these swellings may be found in the new-born child. They all increase in size shortly after birth. Local hypertrophy of the part, which is known as macrodactylia, either general or due to an overgrowth of a single tissue, is likely to be mistaken for a cystic lymphangioma occurring in one of the extremities. Diffuse lipoma is such a condition. But diffuse lipomata are much more liable to be mistaken for cystic lymphangiomata than are the well-defined lobulated swellings. Cystic lymphangioma can be distinguished from diffuse lipoma by the greater tenseness of the lymphatic swelling and by the peculiar elasticity which is recognizable when a number of cysts lie below the skin. The lipomata are softer and more doughy. The skin is more intimately attached to the lymphatic tumor than to the lipoma, unless it happens that the cyst lies beneath the deep fascia, when the skin will be found freely movable. Lymphangiomata usually present prolongations of their tissue which may run a considerable distance either deeply or superficially, or these prolongations may be present as isolated tumors which are separated from the main growth by an area of healthy tissue. Cystic lymphangiomata have also to be distingnished from cavernous nevi and those rare blood-tumors which arise subcutaneously or arise even beneath the muscles as pockets or pouches in the veins. Cavernous nevi only differ from cystic lymphangioma in being developed from the vascular instead of from the lymphatic system, but nevi are more common than lymphangiomata. They can always be reduced in size or even emptied by continued pressure, whilst muscular exertion and all efforts leading to venous engorgement increase their size. Some nevi have a varicocele-like feel, and the skin over some is the seat of capillary nevus. Nevi containing much connective tissue or fat or sarcomatous tissue are hard to diagnosticate from cystic lymphangiomata, and in such cases exploratory puncture may be necessary to give a correct diagnosis.

The author then reports an interesting case of a large lymphangioma involving the whole left side of the face and the upper half of the neck, in which operation was performed with the most successful result.

[The treatment of these cases is open to the widest divergence of opinion. Some cysts, even very large cysts, may disappear spontaneously, but this is a very unusual occurrence. The proper operation is the excision of the tumor. Electrolysis may cure the simpler cases, but at best it produces a fibrous tumor, and, as this will have to be removed, it will leave a scar as pronounced as if excision had been practised upon the original growth. Setons should never be used; puncture and drainage are rarely effectual, excepting in single cysts, such as hydroceles of the neck. In these single cysts puncture and drainage may be tried.]

DISEASES OF THE LIPS, PALATE, AND SALIVARY GLANDS.

The London Practitioner of August, 1895, contains a lecture by Christopher Heath upon the subject of **hare-lip.** He reviews the subject most practically and clearly. He thinks the best period to operate, unless there is some special indication or contraindication, is about the 6th week of life. The operation which he has for a long time employed with success is to freely pare one side of the lip, to cut a flap from the other side, and approximate it. The flap is taken from the longer side of the lip. He sews up with chromicized catgut, and unites two or three stitches through the mucous surfaces as well. The cheeks are drawn together with a strip of adhesive plaster. In order to prevent crying the child is given minute doses of opium and is frequently nursed. During the process of healing the child should be fed with a spoon. In double hare-lip, with projection of the intermaxillary bone, Heath insists that this bone must be cut away, for if it is left it will always be loose and will inevitably cause trouble.

Edmund Owen[1] considers the **operative treatment of cleft palate,** and reports 5 interesting cases to illustrate different aspects of this disorder. In regard to the time at which it is best to endeavor to close a cleft in the lip and in the soft palate, Mr. Owen says that he is choosing an earlier date for his operations. One of the patients in this list was just 2 years old when operated upon for complete cleft. If the speech is to be improved to the utmost, the mouth must be roofed at the earliest moment. A cleft in the soft palate can be closed in the first 6 months. With a hard and soft palate together it can be done in the second year, but he would not be surprised to hear that it may be safely done earlier. He no longer practises the division of operation into two stages, one for the hard palate and the other for the soft. He used to practise this method, but has given it up entirely. It is full of disadvantages, and it does not possess any merit to counterbalance them. Owen is much indebted to Clutton for his views upon the value of early operation.

Raymond Johnson[2] writes an article upon some unusual cases of **swelling of the parotid gland.** The swelling was on one side in each case, and there was no difficulty in excluding swelling due to enlarged lymphatic glands. These cases were obviously not mumps. There had been no exposure to the contagion of mumps. The swellings were far more prolonged, but one parotid gland was affected and there was absence of infection of other individuals. Salivary calculus was not present, neither were the cases to be considered as symptomatic parotitis or parotid bubo, such as may occur in the course of pyemia or typhoid fever. Neither could they be considered as belonging to the group made clear by Mr. Stephen Paget in which parotitis complicates various abdominal diseases and injuries, at times apparently independent of sepsis. His cases were swellings of the parotid gland resulting from interference with the escape of its secretion due to inflammation of the lining of

[1] Lancet, Jan. 4, 1896. [2] Ibid., Apr. 18, 1896.

Stenson's duct. This conclusion was suggested by the fact that in Cases 1 and 2 pressure on the swollen gland caused the escape of a thick flood of mucus from the duct, and this was followed by a free flow of saliva from the duct.

DISEASES OF THE THYROID GLAND.

The British Medical Association in 1895 discussed **the surgical treatment of cysts, adenomata and carcinomata of the thyroid gland, and of accessory thyroids.**

Mr. Butlin[1] said to his knowledge he had never seen a tumor of an accessory thyroid. He cannot but believe that the frequency and importance of thyroid tumors have been exaggerated. He has never removed a malignant tumor of the thyroid, and has never seen one removed, and he has never seen one where there appeared the smallest likelihood of successful radical operation. The examination of all museum specimens shows this statement to be true.

Prof. Keen called attention to the fact that on the continent of Europe thyroid operations were done without the use of anesthetics, except in children under 15 and in very nervous patients. There was very slight pain in the operation. When the anesthetic was given there was less hemorrhage, since the respiration was less laborious and the patient did not cough. During the ligation, in order that it might be seen whether the recurrent laryngeal nerve was included in the ligature, the patient was induced to talk. Prof. Kocher makes a transverse incision, convex downward, so as to get at the thyroid better and leave a well-concealed scar. The use of Halsted's subcuticular suture will obviate unsightly scars. Dr. Keen's own personal trouble in these cases had been hemorrhage. In Switzerland great attention is paid to tying carefully every bleeding point, and not more than 2 ounces of blood are lost during an operation. Kocher cuts right down to the tumor, tying every source of bleeding. He commences extirpation at the upper part, which he can often wipe clean from the surrounding tissues. He next ties the superior thyroid artery and vein, and then goes right down to the thyroidea ima. He finally feels for and ligates both inferior thyroid arteries in succession, and then removes the tumor. [Sutton says positively that all cysts of the thyroid gland arise from adenomata. Enucleation is a comparatively recent treatment, and is the proper method for treating many goiters. Porta devised the operation of enucleating cysts. It is suited to single but not to multiple cysts. Socin is a strong advocate of enucleation, and was the first to apply it to noncystic tumors. Enucleation never causes myxedema, as it does not destroy any normal gland tissue, and in performing the operation the surgeon cannot injure the recurrent laryngeal nerve. The unbroken cyst can be dissected free, or the cyst-wall can be dissected out after the cyst has been incised and emptied. Roeber is an advocate of excision, and maintains that enucleation produces more hemorrhage than a properly performed excision.]

Shepherd[2] reports 16 cases of surgical treatment of certain forms of **bron-**

[1] Brit. Med. Jour., Oct. 12, 1895.

[2] Ann. of Surg., Sept., 1895.

chocele. He considers the forms suitable for operation are cysts and colloidal forms. He prefers the operation of enucleation, and he has done it 16 times without a death. In some cases with very thin cyst-walls enucleation will be impossible, and the cyst-wall will have to be picked out piecemeal, and this will cause profuse hemorrhage. The reasons which indicate operation are the existence of dysphagia, dyspnea, rapid growth, pain, discomfort, and great deformity. In cases where the growth only causes great nervousness it is justifiable to remove it. Shepherd unhesitatingly uses ether, and does not think that it unduly congests the vessels. After the cyst has been removed and the bleeding areas have been tied he packs with iodoform-gauze, and allows the end of the gauze to stick through the lower angle of the wound. He sews up the skin-wound with horsehair and patients leave the hospital about 8 days after the operation.

Mikulicz[1] reports 11 cases in which he operated for **exophthalmic goiter.** In 10 of these cases there was enlargement of the thyroid, and in 1 case a lymphangioma below the chin. The cases that he classes as true exophthalmic goiter were those in which in addition to true tachycardia he found distinct mental and nervous disturbances. Six of these cases he says were cured; 4 were markedly improved. Mikulicz thinks that any operation which decreases the size of the thyroid benefits the case, and may even lead to a cure, although complete cure will not be attained for several years. When the goiter is diffuse the afferent vessels may be ligated or a portion may be resected. In the first 48 hours after operation there is profound disturbance of the circulation and the respiration. [Herskin was operated upon himself and was cured. This surgeon collected 53 cases with 17 cures (over 40%); 3 died, and only 3 were not benefited. In 21 of the patients partial excision was practised; in 3 the arteries were ligated; in 1 iodin was injected; in 3 cauterization with zinc chlorid was employed. Kocher has reported 39 cases, most of which were completely cured, and all of which were greatly benefited, but he afterward had 3 deaths. Stephani divides cases into two groups: 1. Primary aberration of the nervous system, with a vascular enlargement of the thyroid. This should not be operated upon. 2. A genuine goiter exists from the start, and should be removed. Eisendrath has recently reviewed the subject of exophthalmic goiter. Kocher opposes the treatment by ligation of 4 vessels, because it is apt to cause the entire gland to atrophy, but he ligates 3 vessels. Wette holds that a goiter is the cause of Graves' disease, and not a mere consequence; hence, if cure is not soon obtained by medical means, an operation should be performed. He advocates the removal of from two-thirds to three-quarters of the gland. Removal of the entire gland would cause myxedema. Wette cautions us to absolutely arrest bleeding, and to remember that the pneumogastric may be pushed out of place by or be enclosed in the goiter. Trendelenburg of Bonn ties all four thyroid arteries, and has never met with myxedema. Krönlein employs extirpation. Rydygier of Cracow has tied the four arteries in 22 cases, and has

[1] Centralb. f. Chir., xxvii., 1895.

never had myxedema follow. Harsant very ably reviewed this subject in Bristol Med. Chir. Jour., Dec., 1895. The liability to sudden death after these operations is discussed in the *Year-Book* for 1896.]

Bland Sutton[1] reports an interesting case of **median cervical fistula** in the lower third of the neck. There was an opening through which mucus flowed, and a probe was introduced, passed upward in the middle line just beneath the skin, and stopped at the middle of the lower border of the basihyal. It was quite evident that this condition was a persistent thyroid duct. The parents said that it appeared when the patient was 3 years old. It ordinarily caused him no trouble, but during the last 2 years it seemed subject to catarrh, and the excessive flow of mucus caused him so much inconvenience that he was anxious for relief (Fig. 66). Mr. Sutton dissected out the duct. He found it

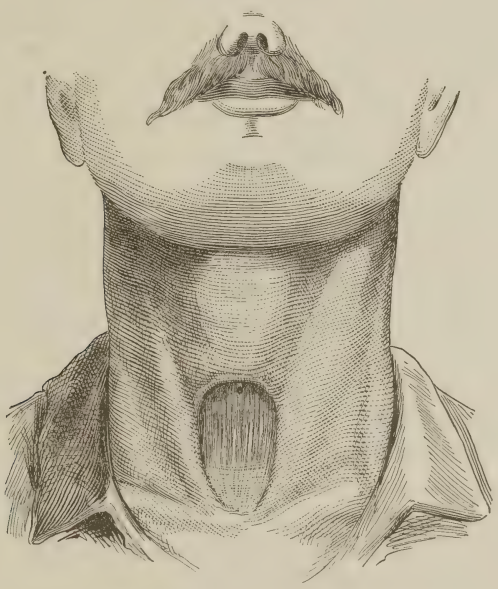

FIG. 66.—Median cervical fistula (Sutton, in Lancet, Nov. 9, 1895).

passed vertically upward beneath the deep fascia of the neck to the basihyal. Near its lower end the duct bifurcated, one arm ending blindly, the other opening on to the skin, as already described. The upward end of the duct passed behind the basihyoid, finally becoming incorporated with the thyrohyoid membrane. By introducing a probe into the duct at the beginning of the operation and keeping it there he was able to remove the duct entire. He sewed up the deep fascia by buried sutures of catgut and sewed up the skin with silk. This case illustrates well the chief features of the thyroid segment of the thyroglossal duct—its median position and relation to the basihyal, and the appearance of the fistula subsequent to birth. It is thus in striking contrast to branchial fistulæ, which are always lateral, in close relation to the sternomastoid muscle, and are always congenital. An examination of this

[1] Lancet, Nov. 9, 1895.

specimen showed that the duct was lined with typical columnar ciliated epithelium; goblet cells were present. The tissue forming the walls of the duct resembled atrophied thyroid tissue; here and there isolated acini lined with epithelium were detected. It is to be noted that the epithelium of the thyroid duct and of persistent branchial fistulæ is identical. This demonstrates that the thyroid duct is a real and tangible structure large enough to accommodate a probe; it is not a minute passage existing only in the embryo.

DISEASES OF THE MUSCLES AND TENDONS.

Buchanan[1] says **rupture of the tendon of the quadriceps extensor femoris** appears to be a rare injury or, at least, rarely recorded, a careful examination of literature disclosing but 120 cases. The most important papers yet published upon this subject are by Maydl of Vienna in 1883, Bull of New York and Hoffman of Berlin in 1889. Bull made a careful study of the cases collected by Maydl and himself, and arrived at the conclusion that when operative treatment was not adopted an imperfect result would occur in half of the cases. Buchanan says that this lesion furnishes the same indications for treatment as does fracture of the patella, but this indication is very difficult to fulfil by external appliances. The upper border of the upper fragment in transverse fracture of the patella furnishes an offset, over which can be looped the turns of muslin, plaster, leather, or other materials used to make traction upon the quadriceps muscle, and thus approximate the fragment; but in rupture of the quadriceps tendon no such purchase exists, and if we treat it without operation, we have to rely on rest in bed in the extended position, bandage of the thigh from above downward, and of the patella from below upward, and the posterior or immovable splint. This method of treatment is very inefficient, and statistics show that its results are poor. The proper treatment is to apply buried sutures through the incision. Buchanan then reports a case in which he obtained a most successful result, and tabulates the 10 cases which have so far been reported as operated on by open incision. The operative method should be recommended to patients.

Walker[2] elaborately discusses the entire subject, and makes an analysis of 255 cases with reference to treatment and the results. He tells us that under mechanical treatment 72.5% recovered completely—12.5% in 3 months and 32% between 3 and 6 months. Under the operative method 86% recovered completely—50% within 3 months and 36% between 3 and 6 months. Thus under the operative method there is a much larger percentage of complete recoveries and the duration of treatment is very much shortened, without any increase of mortality. He concludes that in recent cases without much joint-effusion, and when the joint is apparently not open, where the separated ends can be approximated and held by suitable mechanical adjustments, mechanical treatment can be considered, and in the great majority of cases it will bring about complete recovery, although from 9 to 12 months' time will be necessary to fully reestablish normal functions. Too prolonged retention in bed is unfa-

[1] N. Y. Med. Rec., Nov. 2, 1895.

[2] Am. Jour. Med. Sci., June, 1896.

vorable to early recovery, and early massage and passive motion are strongly advised. The skilful aseptic surgeon who resorts to primary operation in a suitable case may reasonably hope to obtain a better result in a larger number of cases, and save his patient from 3 to 6 months' time. Catgut, kangaroo tendon, or silkworm gut should be used, and when there is much effusion drainage should also be employed. Operation should always be undertaken when there is separation to a greater extent than $1\frac{1}{2}$ in. or when mechanical treatment has failed. In future the operative treatment will be more often indicated and more frequently applied.

Franke[1] outlines the operation of Nicoladoni for making up for a **defect in action of a paralyzed muscle** by dividing the tendon of this muscle and uniting the distal extremity of this tendon with the tendon of a normally acting muscle. This observer reports 2 cases of his own, and cites 15 others, in which this operation gave excellent results. In 1 case of pes equinovarus he cut the tendo Achillis, and found that the foot was still in dorsal flexion. The tendon of the extensor longus digitorum was severed and the distal portion was united by suture to the tibialis anticus. The child had previously been able to get about only with the aid of braces, but was now able to run and play without support. The second case, a child of 5 years, presented equinovarus, but after the performance of this operation was ultimately able to run about without the aid of braces.

G. G. Davis[2] reports 2 cases of rupture of the long head of the biceps muscle. These cases were associated with rheumatoid arthritis, and the patient was unable to place the distinct time at which the rupture had occurred. The cause of the rupture is that the tendons are weakened by the disease. The tendon ruptures and becomes absorbed, and this may occur early in the attack of rheumatoid arthritis, long before the marked change that one sees in the familiar illustrations in the text-books.

Injuries to the Tendons of Fingers.—Walkace[3] reports a case of a woman of 29, who found she was unable completely to extend the last phalanx of the middle finger of the left hand. A few hours previously she had caught her finger while pulling on her stocking, and had heard a snap, though she felt no pain. On attempting extension the terminal phalanx formed an angle of 135° from the rest of the finger. There was a tenderness and swelling over the back of the joint and some pain over the middle of the dorsum of the middle phalanx. A splint was applied and kept on for about 10 days, after which a splint with a spring which pressed back the terminal phalanx was kept on for a fortnight, producing an angle of 160°. [We know of a similar injury occurring in a physician in which the finger was 6 months in returning to a normal condition, and the joint was tender and weak for 2 years.]

Kidd[4] reports 2 cases of rupture of the terminal expansion of the extensor communis digitorum. The joints in the long run practically recovered power of expansion without any specially applied treatment. Thomas[5] reports a

[1] Med. News, May 23, 1896. [2] Ibid., Aug. 3, 1895.
[3] Lancet, Feb. 29, 1896. [4] Ibid., Mar. 28, 1896. [5] Ibid., May 9, 1896.

case of rupture of the terminal expansion of the extensor communis digitorum which was similar to those previously set forth. Walsham[1] writes on the treatment of dislocation of the tendon of the peroneus longus. He tells us that this accident may happen suddenly or gradually, and that the tendon slips from the gutter behind the outer malleolus and lies upon the outer surface of the malleolus. The condition causes much suffering and inconvenience, and the treatment by the application of pads is absolutely insufficient. Walsham opposes dividing the tendon for the purpose of creating adhesion to the sheath, because such a procedure destroys the function of the tendon. He makes a new sheath for the tendon, the sheath being composed of fascia and periosteum, which is lifted up from the lower end of the fibula. This flap is carried across the tendon and sutured to fibrous tissue back of the proper groove. This surgeon reports a successful case.

FRACTURES AND DISEASES OF THE BONES.

FRACTURES.

A form of splinting is strongly recommended by Edward A. Tracy[2] in an article designated **"The New Surgical Splinting."** It is composed of crushed wood-fiber rolled in a rugose fashion in which some fabric has been incorporated. This material may be readily moulded to fit any part. Before application it is moistened with water or with a solution of potassium silicate, the ordinary solution of silicate being taken after dilution with one-half its bulk of water. When moist the material is applied directly to the limb and bandaged so as to make it conform to the shape of the part. It is then removed and dried over the kitchen fire or a gas-jet, and it is reapplied to the limb before being completely dry.

Bardeleben[3] made a report on **early motion in fractures,** especially in the lower extremities. In the past year he has treated 58 cases, making a total of 181 fractures in which this method has been employed. A good result was obtained in every case. The time required for healing was shorter than when the patient is confined to his bed, and by this method there was escape from the danger of muscular atrophy from protracted disuse and bronchial catarrh from prolonged recumbency.

Krause[4] made a report upon the **ambulatory treatment of fracture.** He tells us that in fracture of the ankle the dressing should reach as high as the head of the tibia or even above the knee-joint. In fracture of the leg the dressing should be carried to the middle of the thigh, and in fracture of the lower end of the femur the dressing must be carried to the lower end of the pelvis. He keeps the patients in bed for one or two days in the beginning of treatment. In estimating the duration of treatment he concludes that there is no particular difference in duration between ordinary treatment and ambulatory

[1] Brit. Med. Jour., Nov. 2, 1895.
[2] Jour. Am. Med. Assoc., Jan. 25, 1896.
[3] Beilage z. Cent. f. Chir., 1895, No. 27.
[4] Centralbl. f. Chir., vol. xxii. p. 685, 1895.

treatment, in fractures of the fibula and in fractures of the leg the average duration being $38\frac{3}{4}$ days, the ordinary treatment requiring $47\frac{1}{2}$ days to obtain consolidation. In fracture of the leg, middle and lower third, the duration has been $41\frac{3}{5}$ days up to consolidation; under the older methods of treatment it was $71\frac{1}{2}$. He calls attention to the fact that the period at which the plaster bandage has been removed has not always corresponded with that of consolidation. Instances of delayed union occasionally happen during this ambulatory treatment, especially in 1 case of complicated fracture of the leg in a laborer 62 years of age, where consolidation was delayed to the 115th day, but in most instances consolidation was more rapid than usual.

In the Congress of French Surgery[1] Heydenreich gave a resume of the **operative treatment in recent fractures.** He was not disposed to strongly advise operative treatment in recent simple fractures.

Berger stated[2] that in simple fracture of the shafts of most long bones operation had not been proposed with seriousness. It was proposed for broken clavicle and broken leg. Berger opposes suturing the clavicle unless injury of the nerve or vessel complicated the injury of the bone. He considers that ordinary treatment gives satisfactory results. Operative treatment is followed by a scar which is itself decidedly objectionable, and is apt to be attended by considerable swelling because of the formation of callus. He states that when we are dealing with an oblique fracture of the leg no apparatus is known which will ensure union without shortening. Berger thinks that suturing these bones together would fail to overcome the shrinking which arises because of obliquity of the fragments and the action of the flexor muscles; and he thinks, further, that not only would osseous sutures fail to correct the difficulty, but would be fraught with considerable risk. It is a well-known fact that when bones are sutured there is likely to be an excessively sensitive callus, and the leaving of metallic sutures in bones may lead to grave troubles. He thinks that even in the worst forms of simple fracture of the leg we should content ourselves with careful management as to details. The plaster-of-Paris apparatus should never be applied immediately, and reduction should be brought about gradually and not attempted suddenly, and an immovable dressing should be applied when reduction is complete. The only cases in which Berger thinks a surgeon is justified in making an incision, replacing the fragments and suturing them, is when the inability to effect reduction is due to the presence of loose bone or portions of muscle, periosteum, or ligament between the fragments. Berger says that in articular fractures those only in which operation is justifiable are about the elbow and knee, because an imperfect result here means a most grave functional loss. He very greatly doubts whether the functional result could be improved if we were to suture the fragments of a fracture of the elbow-joint. In fracture of the condyles of the femur suture is more certainly indicated, but the dangers which arise from infection of the knee-joint are so great that he does not advise operation unless the displacement positively resists reduction and is very marked. Berger of course excludes in these remarks

[1] Reported in La Semaine méd., Oct. 26, 1895. [2] Méd. moderne, Nov. 2, 1895.

operations upon the olecranon and the patella, which are very frequently advisable. [Reynier opposed Berger's contention that a fracture of the clavicle should not be sutured, and maintains that the operation is not unusually indicated, especially in women. Boeckel stated that in some cases of fractured clavicle nothing but suture could secure even a fair result, and Demours and Villar agreed with him, asserting the same to be true of the lower jaw. Two recent cases were sutured by Hearn in the Jefferson Hospital in which it was found impossible to correct the deformity before operation. The fragments were disentangled and were sutured with kangaroo tendon, and the skin was closed with a subarticular stitch. The result in each case was admirable: deformity was absent, there was complete use of limb, scar was so slight as to be scarcely visible, neither scar nor callus was painful. When reduction of the deformity cannot be accomplished by posture and manipulation, when reduction cannot be maintained by the use of an apparatus or confinement in bed, when pressure is being made by the fragments upon the great vessels or nerves, when the fragments threaten to perforate or have perforated the skin,—suturing should be performed, and we should use kangaroo tendon, as did Hearn.]

Viana[1] in making a **diagnosis of fracture** in difficult cases suggests the old idea of Lisfranc of employing **auscultation.** The surgeon places the stethoscope near the supposed fracture and makes percussion adjacent to the stethoscope. This percussion should be made with a hammer and plexiimeter, and is carried along the bone. At the minute it is applied over the seat of fracture a decided change in the resonance is easily noted. This method of diagnosis is said to be of value in fracture of a bone of an extremity, the skull, and a rib.

Harte[2] writes upon **epiphyseal separation of the lower end of the femur,** and reports 5 cases of this rare and interesting accident. Hamilton only saw 1 case of this injury.

Stokes[3] regards the diagnosis of **fractures of the upper third of the femur,** including the neck, as frequently very difficult. When we remember that at times many of the signs and symptoms of fracture may be present without a fracture, and that, on the other hand, fractures may exist without many of the signs and symptoms, it becomes obvious that diagnosis is difficult. There is no group of fractures in the vicinity of the joint in which there is a greater variation in the size. In the majority of cases there is some shrinking of the limb. In others this is scarcely perceptible, and in one form it has been said that slight lengthening may occur. In most cases there are eversion and abduction of the limb, but in others there is neither one nor the other. In the third group there are inversion and adduction. In some there is pain; in others there is freedom from it. Immediate shortening is the rule in fractures of the cervical base, but frequently in fractures of the cervix shortening is of secondary development. In fractures of the base impaction occurs in some cases, and is absent in others. In fractures of the cervix proper we do not have impaction, but have penetration. In some cases the fracture results from fall:

[1] Gaz. degli Ospidali, No. 63, 1895. [2] Am. Jour. Med. Sci., June, 1896.
[3] Brit. Med. Jour., Oct. 12, 1895.

in other cases the fall results from the fracture. In some cases exuberant bone-growths occur; in other groups absorption of bone takes place. Death from hemorrhage in fracture of the bone has been observed by Cruveilhier, R. W. Smith, Vidal, and others, but it has not been observed in connection with fractures of the cervix. Comminution is a frequent complication in one group, and is rarely if ever observed in the other. Fractures of the cervix take place, as a rule, in the more advanced periods of life, although Sutton has shown that in rare instances they may occur even before the junction of the epiphyses. The most serious of these injuries often results from trivial force; a less serious fracture may result from greater force. All of these circumstances prove the truth of the dictum of R. W. Smith, that each particular symptom of fracture of the neck of the femur, separately considered, must be looked upon as equivocal; the union of all can alone lead to the formation of a correct opinion as to the nature and seat of the injury. Most of the modern surgical text-books fail to allude to the important anatomic structure connected with these fractures—that is, to the fibrosynovial envelope of the cervix, the so-called cervical ligament of Stanley and Smith.

Stokes publishes a table of what he thinks should be the accepted classification, adopting many of the subdivisions of intracapsular and extracapsular fracture suggested by the late Prof. Gordon of Belfast. He thinks that a distinction should be made between fractures with and without penetration and fractures with and without impaction—such a distinction as was made by Prof. Chiene in connection with fractures of the lower end of the radius. This classification was made from specimens belonging to the museum of Queen's College, Belfast, and pictures of the different ones are contained in the article:

Fracture of Cervix Femoris (Intracapsular).

I. Fracture with penetration of cervix into head.	With penetration.
II. Fracture with reciprocal penetration.	
III. Intraperiosteal fracture of cervix at junction with head (transverse).	Without penetration.
IV. Intraperiosteal fracture at center of cervix (transverse).	
V. Extraperiosteal fracture with laceration of cervical ligaments.	

Fracture of Base of Cervix Femoris (Extracapsular).

I. Fracture of base of cervix with partial impaction (posteriorly).	With impaction.
II. Fracture of base with complete impaction.	
III. Fracture of base with partial impaction above (angle obtuse).	
IV. Fracture of base with partial impaction below (shaft split).	
V. Longitudinal splitting of cervix.	Without impaction.
VI. Comminuted fracture without impaction.	

Among the fractures of the cervix there is no doubt that the fifth variety is the one that is most frequently met, and the one in which osseous union, owing to deficient nutrition, nonapposition of the fragments, synovitis, effusion of blood, and rapid interstitial absorption, never takes place. The frequent occurrence of this result doubtless caused the late Sir Astley Cooper and others to fall into the error of maintaining that osseous union never occurs in any intracapsular fracture. We now know that in a considerable proportion of these cases osseous union is obtained. The speaker then showed some beautiful examples of this from the museum of the College of Surgeons and from the museum of the Royal University of Ireland and that of Queen's College, Belfast. Osseous union will occur when the cervical ligament is intact and when one of the two forms of penetration exist; that is, penetration of the cervix into the head, or reciprocal penetration. It therefore appears that there are four different forms of fracture of the cervix in which bony union is possible, provided the usual routine expectant treatment is abandoned. It may with truth be held that the farther from the base of the cervix the lesion is, the less is the chance of osseous union, because the nearer we get to the head of the bone, the more profoundly is nutrition affected, because the nutrition of the parts near the head is chiefly derived through the cervical ligament, which is, as a rule, more or less torn or contused. In injuries high up in the cervix the difficulty of maintaining fixation or rest is more prominent, owing, among other things, to the rarity of penetration which is observed the nearer the lesion is to the head. In the second group of fractures of the cervical base impaction in some form or other is the rule, and the amount of eversion depends upon the amount of impaction. The most usual is impaction of the posterior cervical wall into the cancellous structure underneath the posterior. The theory that the eversion is due to rotation of the shaft upon the base of the neck is, according to some, untenable, they holding that it is due to the rotation of the base of the neck upon the shaft. The occasional occurrence of inversion in both groups of fractures of the cervix and its base is more difficult to explain. Guthrie held that this unusual condition was confined to the extracapsular forms of fracture when the great trochanter or a portion of it remained continuous with the shaft of bone, but Guthrie's statement has been proved an error, as the condition has been observed in fractures of the cervix within the capsular ligament. The late Professor Pirrie published a very remarkable case of inversion of the limb in a case of fracture of the cervix close to the head at right angles to the axis of the neck. The patient died 6 weeks afterward. Postmortem showed that the capsular and iliofemoral ligaments were uninjured, and Prof. Pirrie attributed the deformity to the tension of these ligaments. This does not seem to Sir William Stokes to satisfactorily explain this condition.

R. W. Smith held that when inversion arose it was due to the altered action of the adductors, which became rotators inward, owing to the lower fragment being displaced in front of the upper, so that the insertion of these muscles was in a plane anterior to their origin. If muscular action were the cause, how-

ever, the inversion would continue constant, but such is not the case. It occasionally happens that inversion is well marked, and a day or two later the usual eversion supervenes. Stokes thinks that the inversion is most probably due to the limb having been adducted and inverted at the time of the accident, and that afterward the limb remained in the position it was at the time injury was received.

Fracture of base of cervix (extracapsular).	Dislocation on dorsum ilii.	Fractures of the brim of acetabulum.	Fractures of fundus of acetabulum.	Contusion.
Common in advanced life.	Rare in advanced life.	. . . . .	. . . . .	Relation between anterior subspine and trochanter on both sides, the same at first.
History of direct fall on trochanter.	History of forced rotation inward of femur.			
Shortening.	Shortening greater.	Shortening.	Shortening.	Preexisting chronic rheumatism, a cause of great difficulty in forming a right estimate of the case. Note the previous history, and observe that the powerless state induced by the injury soon passes off.
		Shortening recurring after extension is removed.		
Eversion usual.	. . . . .	Inversion.		
Inversion rare.	Inversion constant.			
Inversion slight (Guthrie).	Inversion well marked.	Power of eversion.		
		Adduction.		
Movements comparatively easy.	Movements difficult and restrained.	Power of widely abducting limb.		
		Flexion of knee.		
Head in acetabulum.	Head on dorsum ilii.	Head drawn upward and backward, with detached fragment at brim.	Head passes into pelvis.	
Outer surface of trochanter, looking backward.	Approximation of trochanter to anterior subspine.	Crepitus.	Fracture comminuted, star-shaped.	
Pain along line of fracture in front, above, and behind.	No pain on pressure over trochanter.	. . . . .	Liability to formation of abscesses in iliac fossa.	
Diminished tension of extensor muscles (Lagoria).	Increased tension.	. . . . .	Accident generally fatal.	

There is no part of the subject more important than a differential diagnosis, as the patient's future and the surgeon's reputation depend upon a correct estimate of the condition. Fracture of the cervix may be mistaken for luxation on the dorsum ilii, fracture of the brim of the acetabulum, fracture of its fundus, and contusion. The differentiation may generally be made by bearing in mind that in fracture we have usually a history of a direct fall on the trochanter, followed by eversion, shortening, and backward dissection of the outer surface of the trochanter, occurring in advanced life, with marked pain along the line of fracture, diminished tension of the extensor muscles, and occasional inversion; that in a dislocation we have a history of forced internal rotation; that dislocation is rare in advanced life, shows great shortening,

usually inversion, approximation of the trochanter and the anterior superior spine, the presence of the head of the bone on the dorsum of the ilium, difficult and restrained movements, absence of pain on the trochanter, increased tension of extensor muscles, and constant and decided inversion. In fractures of the brim of the acetabulum we have the head drawn upward and backward, with a detached fragment of the brim, shortening, inversion, crepitus, adduction, recurrence of shortening after extension is removed; we furthermore have the power of eversion and abduction of the limb. In fractures of the fundus comminution is usual. When a head passes into the pelvis shortening is noted, there is a liability to abscess-formation, and generally a fatal result. In contusion the normal relations between the anterior superior spine and the trochanter are at first preserved, though ultimately are often lost. The knowledge that chronic rheumatism preexisted often adds to the difficulty of a differential diagnosis. The preceding table of differential diagnosis is of value.

From all considerations Stokes thinks we are justified in forming the following conclusions.

1. The alleged senile alteration in the angle between the axis of the cervix and the shaft of the femur does not occur, and cannot therefore be regarded, as it has hitherto been, as a predisposing cause of fracture of the cervix femoris.

2. That the process of absorption in the case of fracture is probably due primarily to senile osteoporosis, and secondarily to the twofold action of the absorbents on the one hand and friction of the broken fragments on the other, and, in the case of contusion, of impaired nutrition consequent on a low form of synovioperiosteal inflammation.

3. That in classifying fractures of the cervix or its base a distinction should be made between those with and without penetration and those with and without impaction.

4. That osseous union may take place in 4 out of the 5 different forms of fracture of the cervix femoris.

5. That the farther the fracture is from the base of the neck the less is the probability of osseous union.

6. That fracture of the cervix may occur previously to epiphyseal junction.

7. That the differentiation of these injuries lies between fracture of the cervix or its base, luxation, fracture of acetabular brim or acetabular fundus, and contusion.

8. That the principles of treatment should be fixation, rest, and moderate extension.

The paper of Southam alluded to in the previous article by Stokes[1] is designated "**The Treatment of Impacted Fracture of the Neck of the Femur** by Breaking down the Impaction under Anesthesia." In his first paper[2] he called attention to the unsatisfactory results which attend the usual method of treating impacted extracapsular fracture of the neck of the femur. This treatment consists in keeping the limb at rest and making no attempt to correct the deformity. The result is that the patient remains for life with a limb that is shortened and everted. He describes the case of a man of 27, in which the fragments were forcibly loosened while the patient was under anesthesia and the deformity corrected, with the result that perfect union took place. He reports in this paper 3 cases which have recently been treated by the same method in the Manchester Royal Infirmary (2

[1] Lancet, Dec. 21, 1895. [2] Ibid., Nov. 17, 1894.

under the author's care and 1 under Mr. Whitehead's). The result in each case was satisfactory. The patients were aged respectively 50, 75, and 65 years. These cases illustrate the fact that advanced age is no bar to this procedure, the fracture in each instance readily uniting, with abundant formation of callus, after the breaking down of the impaction.

Barker [1] discusses the permanent **subcutaneous method of wiring the patella** for fresh transverse fracture. The method has given him great satisfaction. In order to get the best results certain measures of general treatment are necessary, and certain details in the application of the suture must be carefully attended to. This operation is of course only suited to recent fractures, and it should be done as soon as possible after the injury. Passive motion, even slight active motion, is permitted immediately after the operation. In his earlier cases Barker splinted the limb for a few days. He has now abandoned this procedure, and thinks it even harmful, except in patients who are drunk or who are suffering from delirium tremens. The patient is told that he can move his leg about in the bed as much as he likes if it is not painful. In addition to this, the surgeon daily makes passive flexion. Massage is begun the day after the operation, and is continued for a couple of weeks. The material employed for suture is silver wire. Silk was used in 2 cases, but it was found difficult to obtain a close and tight approximation with silk.

"The wire I have always employed is of soft silver. In thickness it is just equal to a No. 1 silver English catheter. The exact thickness by wire scale I do not know, but this measurement is accurate enough. A piece of this about a foot long should be straightened, and then softened by heating in a spirit flame.

"And now as to the adjustment of the fragments. Before the wire is introduced the operator takes each fragment between the finger and thumb of opposite hands. He always stands on the patient's right side. He then proceeds to rub the fractured surfaces one against the other, which in fresh fractures is easy enough. Thus rubbing them from side to side, he is soon conscious that he has dislodged all blood from between them or clot and fibrous material, and that they grate one against the other like dry lumps of sugar. When he gets this sensation he is ready to introduce the wire. Then, while he is preparing to close the wire on the fragments as above, his assistant repeats the rubbing process, and finally brings the fractured surfaces accurately together, with special care that the external and internal edges correspond and that there is no rotation of either on its vertical axis. The closing of the wires keeps them in the same plane, one passing over the front and one over the back of the fragments. Then the wires are twisted as above. Care should be taken that the first twist should not be too sharp, lest the wire be snapped. This occurred in one case with a thinner wire, and I had to introduce a second wire. The second and third twists will tighten the first.

"And now let me once more briefly describe the steps of the operation, bearing in mind the emphasis to be laid upon the matters of principle and detail mentioned above:

"First, everything about the field of operation and the instruments, etc. is made aseptic. Then the lower fragment is steadied between the operator's left finger and thumb, while a narrow-bladed knife is thrust exactly through the middle of the upper attachment of the patellar ligament, with its edge upward cutting on the bone. When the blade has entered the joint it is withdrawn, still cutting on the lower edge of the lower fragment, and enlarging the skin wound upward to the extent of two-thirds of an inch. Through this opening a special long stout-handled needle, without any wire (Fig. 67), is now thrust into

[1] Brit. Med. Jour., Apr. 11, 1896.

the joint behind both fragments, and is made to pierce the tendon of the quadriceps close to the upper edge of the upper fragment, exactly in the middle line of the fragment. When its point appears under the skin it is cut down upon with the knife, whose edge

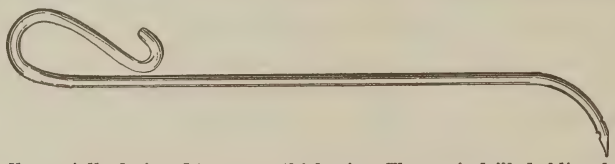

FIG. 67.—Needle specially designed to carry a thick wire. The eye is drilled obliquely, and should receive only a little loop on the end of the wire; this little loop should be made previously (*vide* Figs. 68 and 69) (Barker, in Brit. Med. Jour., Apr. 11, 1896).

should now be turned downward and enter the joint beside the needle, cutting upon the upper edge of the upper fragment, so as to leave nothing between the needle and the bone. A stout silver wire (*b*) is now threaded through the eye of the needle (Fig. 68), and the

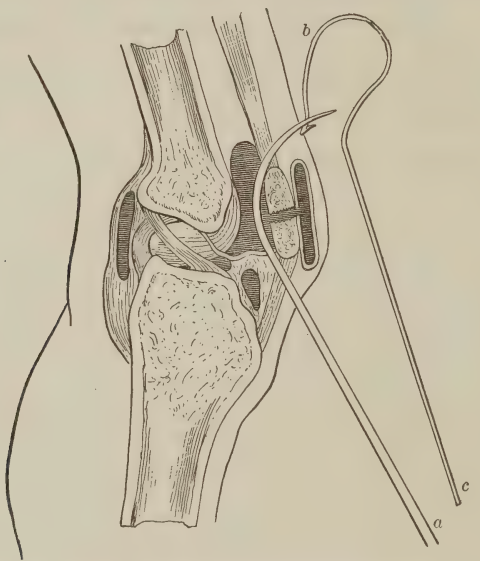

FIG. 68.—Needle (*a*) introduced behind the fragments, and receiving one end (*b*) of the silver wire (*b*, *c*) (Barker, in Brit. Med. Jour., Apr. 11, 1896).

latter is withdrawn and then unthreaded. The empty needle is then again thrust through the same lower opening, but this time in front of and close to both fragments, until it emerges through the upper puncture. Here it is threaded with the other end of the wire (*c*), and is withdrawn (Fig. 69). Both ends of the wire now emerge by the lower opening. I then thread each through holes in the center of short metal bars (Fig. 70) for the convenience of pulling, and fix their respective ends to the bars by a second transverse threading. Then the posterior wire is drawn upward and the anterior downward, as described above (Fig. 70). When the fragments are adjusted the bars enable the surgeon to make a powerful even strain on the wires and twist them as above accurately. While the wires are in situ, but before they are twisted, all the blood in the joint should be squeezed out by pressure with the hands and kneading. The whole operation should not take more than five minutes from beginning to end.

Cox[1] offers some considerations in regard to the **operative treatment of fracture of the patella.** He maintains that there are some cases which

[1] Ann. of Surg., Dec., 1895.

obviously do not require operation. If in 24 hours the joint is found much distended, we should operate and open the joint. The operation he prefers is to bare the bone and suture the fragments with catgut. He thinks that either

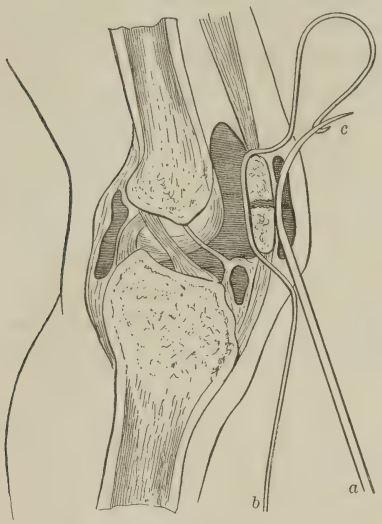

FIG. 69.—Needle (*a*) passed in front of the fragments, and receiving the other end (*c*) of the silver wire (*b*, *c*) (Barker, in Brit. Med. Jour., Apr. 11, 1896).

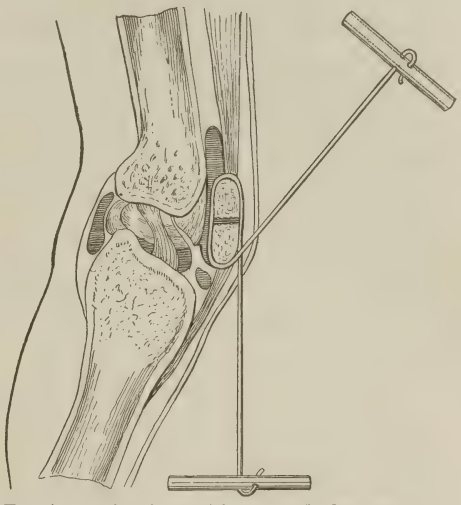

FIG. 70.—Wire in position round fragments and threaded through metal bars. The lower and posterior wire runs upward to the left of the upper ready for twisting (Barker, in Brit. Med. Jour., Apr. 11, 1896).

silk or silver wire, if employed as a suture, is likely to lead to subsequent trouble, to sinus-formation or to caries. He uses catgut which is reinforced by the sustaining external dressing. The spasm disappears after 48 hours, and catgut will not be absorbed for certainly 4 or 5 days. The joint should not be washed out with any irritant antiseptic, not even with distilled water, for irritant antiseptics or distilled water injures the joint-endothelium and interfere with nutritive activity and the energy of the lymphatic system, and hence actually predisposes to subsequent infection. Influenced by McBurney's paper upon the use of normal salt-solution, he has been led to employ this in washing out the joint.

White,[1] as regards the Operative Treatment of Fracture of the Patella, inquires—1. Are the results obtained by the ordinary methods of treatment satisfactory? and he decides that in most instances they are not. He inquires —2. What are the causes of failure? The alleged causes of failure may be divided into 3 classes: 1. The separation of the fragments by the contractions of the quadriceps and the presence of fluid within the joint; 2. The atrophy of the quadriceps, which Von Bergmann believes is due to the pressure of the dressings employed and to disuse. This is responsible for some of the cases in which it is impossible to extend the limb; 3. The cause which Macewen believes is the chief one, the interposition of fibrous and aponeurotic structures between the fractured surfaces. White used to think that Macewen's expla-

[1] Ann. of Surg., Nov., 1895.

nation was the correct one, and that the only rational treatment was to open the joint and elevate the soft parts. The other conditions can be met by simpler and safer means. The exudation in the joint may be removed by aspiration. The fragments can be brought together and held in position by bandages or by Malgaigne's hooks. If Macewen had been mistaken in assigning to the influence of the prepatellar structures the majority of cases of non-union, the aseptic use of Malgaigne's hooks would be the most rational method of treating transverse fracture of the patella. In 1891, Barker introduced his operation, which White has adopted in a number of cases and has found most satisfactory. He has not invariably gotten bony union, but has done so in the great majority of cases, and in 1 case only has there been extensive separation of the fragments resulting. In estimating the comparative value of methods of treatment the danger to life should exert a predominant influence over our selection, and this danger is undoubtedly greater by wiring than by any other plan of treatment; and it is this fact which causes careful surgeons to hesitate in recommending its employment.

A few years ago Dennis compiled a table of 186 cases subjected to wiring. In this group there were 34 cases in which suppuration occurred, 4 in which amputation became necessary, 24 in which the result was poor, and 11 cases terminated fatally; 35 were marked as ending with a fair result, 17 of them having partial ankylosis. The opposition among surgeons at this period of time was very strong, and the procedure was condemned by Bryant and Adams, Henry Morris, Edmund Owen, and other prominent authorities. As late as 1887 we find Barker, Thomson, Stokes, and Robson opposing indiscriminate performance of the operation. White believes that with proper care Barker's operation meets the indications, and that along with a *reasonable degree* of safety it gives far better results than do other methods.

Keen[1] reports 3 cases of **wiring the patella for old fracture.** In these cases the fragments were very widely separated, and in order to approximate them it was necessary to divide the quadriceps muscle, and in 2 of the cases to also chisel loose the tubercle of the tibia. The result in each case was excellent. Keen concludes that these cases are strong arguments in favor of a combined triple operation of wiring the fragments, cutting the quadriceps, and chiselling the tibial attachment of the ligamentum patellæ when the two fragments cannot otherwise be brought into apposition. No reaction of a troublesome nature ensued in any case, and the only unfavorable point was in connection with the section of the quadriceps at the upper end of the incision. To obviate this he suggests the following modification of technic. He says, first, that he will hereafter make a flap of skin beginning on a level with the upper border of the patella and extending downward an inch below the tubercle of the tibia. When this flap is dissected up, the operative procedures can be undertaken as usual, and then the line of union of the patella and the wire and the point at which the tubercle is chiselled loose will not be exposed to possible infection or other accident by lying immediately beneath the line of

[1] Ann. of Surg., Nov., 1895.

incision, but will be entirely covered by a solid flap. If it is necessary to divide the tendon of the quadriceps or of the rectus alone above the patella, this may be done by an entirely independent incision, which can be drained if need be, and the possible contamination of the knee-joint by accumulation of blood-clot through the long incision will thus be avoided.

Phelps [1] concludes that the **obstacle to union** is usually the intervention of the anterior capsular fibers, which get between the fragments, and that this obstacle in most cases cannot be removed without opening the joint; that opening the joint is free from danger; and that by this operation we invariably obtain osseous union in less than half the time required for ligamentous union by other methods. Careful after-treatment means restoration of the functions of the joint, and with the surgeon of ordinary operative skill this is not an operation of choice, but of obligation. [Fowler maintains that before operating we should wait until the injured soft parts have regained a normal standard of nutritive activity, the waiting period being used to asepticize the skin about this region—skin notoriously hard to cleanse because of

FIG. 71.—1, 1, Plaster splint as applied to leg; 2, upper border of splint pressing lower fragment into position; 3, lower fragment with line of fracture above (Bryant, in Med. News, Jan. 7, 1893).

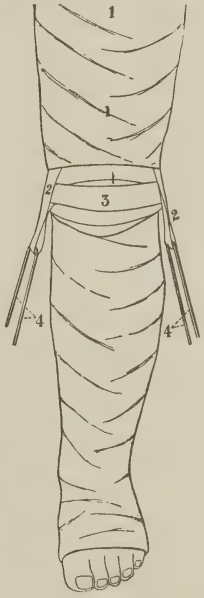

FIG. 72.—1, 1, Extension as applied to thigh; 2, 2, front view of extension straps; 3, adhesive straps retaining fragments in position; 4, 4, rubber extension made taut while adhesive straps are being applied (Bryant, in Med. News, Jan. 7, 1893).

its thickness and the number of creases. Fowler disapproves of wiring (suture through fragments) and tying (suture around the fragments), but after cleaning the ends of the fragments he brings them in contact by fixation-hooks. Fowler does not irrigate the joint, closes the wound without drainage, and applies a plaster cast (see Annals of Surgery, 1895, xxi. No. 6).]

[In many cases of fractured patella careful mechanical treatment will give

[1] Yale Med. Jour., Dec., 1895.

a satisfactory result. Bryant has devised a most useful apparatus which gives continuous extension and allows the patient to be out of bed. Bryant's article was originally published in the Medical News for Jan. 7, 1893. The illustrations (Figs. 71–74) will make the principle of the apparatus evident. A plaster splint is applied to the leg so as to press into position and hold there the lower fragment (Fig. 71). When this splint has hardened the remainder of the apparatus is applied. An extension apparatus made like Buck's exten-

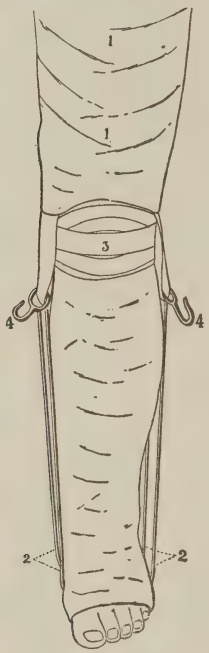

FIG. 73.—1, 1, Plaster bandage applied around thigh extension; 2, 2, rubber extension in position and action; 3, patella-retaining straps; 4, 4, hooks for rubber extension bands (Bryant, in Med. News, Jan. 7, 1893).

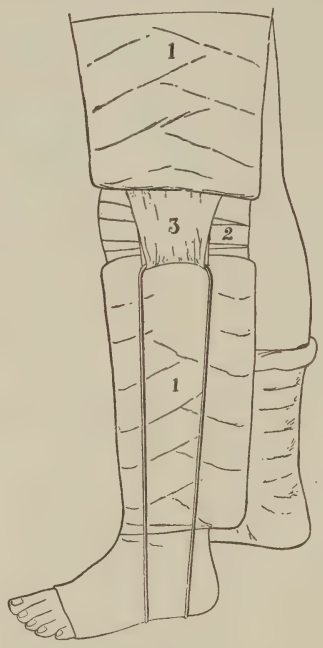

FIG. 74.—1, 1, Upper and lower segments of interrupted splint; 2, posterior support of splint covered by retaining straps; 3, side view of extension strap (Bryant, in Med. News, Jan. 7, 1893).

sion is placed upon the thigh. It reaches from the perineum to the upper border of the upper fragment (Fig. 72). The fragments are now strapped with plaster, the strips being fastened behind to a wooden support (Fig. 72). The fragments are thus drawn well together and supported. While the strips are being applied traction should be made upon the thigh. The next step consists in fastening the posterior support (Fig. 73) in place by means of plaster-of-Paris bandages. We thus form an interrupted plaster splint with a posterior connecting brace. The patient is permitted to walk about upon crutches, the limb being a little flexed and being supported by a long string from the neck.]

DISEASES OF BONE.

An interesting **osteoplastic operation** for loss of substance of the tibia is reported by Lilienthal.[1] There had been a considerable loss of substance

[1] Med. News, Apr. 4, 1896.

in the tibia from injury to the fibula, which remained intact. Ten months after the injury Lilienthal operated by sectioning the fibula and carrying the upper end of the lower fragment of the fibula against the lower end of the upper fragment of the tibia, and suturing it in position. He obtained an excellent result, which was well shown by a skiagraph.

Battle[1] writes a valuable article upon the treatment of **acute inflammation of bone** and its joint-complications. Clinically, 3 groups of these cases are recognized: 1. Those cases which are almost certainly fatal from the first, owing to the general infection. If life is prolonged more than 3 or 4 days the bone-inflammation may be localized as the signs of it have time to develop, but sometimes the bone-disease can only be found, even after death, by a careful search; 2. Those cases of a mild type in which there are evident local symptoms of bone-inflammation, but in which the general disturbance is slight, and in which under appropriate treatment recovery may ensue without any operation. The bone may become thickened in the region of the epiphyses, and lengthening may follow from overgrowth; 3. The third group contains the larger number of cases. The great feature of this group is that treatment may be successful even in the most severe conditions. In some of them there is great danger of pyemia, but in all of them much can be done to prevent it. In the worst cases there is a danger of joint-infection, of involvement of more than one bone, of extensive necrosis of the bones attacked, and of death from hectic or from amyloid disease caused by the prolonged suppuration. The patients are young, however, and it is often possible to save both the life and limb even in desperate cases. The most marked symptom is pain accompanied by fever. The pain is not easily localized at first, but it gradually increases in intensity at night, so that the child cannot sleep or move or permit any one to approach without cries of apprehension. Swelling and edema soon appear, and are most marked near the epiphyses. There is agonizing tenderness, and delirium soon sets in. In severe cases the aspect of the child is characteristic. There is a look of utter, hopeless misery and suffering, and the pale drawn face with sunken eyes looks years older than it should do. The pain is out of proportion to what could occur in any disease with which a physician might confound this condition.

Battle has seen cases sent to the hospital for treatment of acute bone-inflammation when there was nothing more serious the matter than lymphangitis, cellulitis, or erythema nodosum. The mistake, however, is usually committed in the other direction. The disease is sometimes mistaken for acute rheumatism, and the patient is treated with rheumatic remedies until irreparable mischief has been done. The condition of joint-disease which most closely simulates an acute inflammation of bone with secondary involvement of the joint, such as that we have been considering, is gonorrheal arthritis; but that is an involvement of later life. Having once come to a conclusion that we are dealing with a case of acute inflammation of bone, energetic treatment should be begun at once. Leeching the part, following this by the application

[1] Lancet, Nov. 30, 1895.

of hot fomentations, the use of a splint, and the administration of a purgative, will sometimes relieve or arrest the disease. If this treatment fails to abate the symptoms, or if the patient is not seen until the suppuration has begun, an incision should at once be made through the periosteum at the area of greatest tenderness. Usually there will be a flow of turbid fluid or of pus, but if not, the periosteum should be separated in the direction of the epiphyseal line, when the fluid will escape. In many instances the application of a trephine to the diaphysis has been most advantageous. Not only will early operation limit or prevent necrosis, but it will also sometimes prove effectual in saving a neighboring joint from invasion. The surgeon must never wait for fluctuation. Battle then reports 8 cases of extreme interest and practical importance.

Macnamara[1] deals with **infective and tubercular osteitis as causes of arthritis** in childhood and the importance of their early treatment. The paper is a careful study of the subject, and will well repay perusal.

Von Bergmann[2] has had an experience with over 150 cases of **acute osteomyelitis.** He advises free incision of the soft parts, the opening of the bone itself, and the removal of all infected areas. Not only should the medullary cavity be explored, but also the cancellous ends of the bones. When the general symptoms are of great severity and the medullary cavity is filled with miliary abscesses, total resection of the bone must be done. In some instances after resection of the sheath of the long bone there will be insufficient regeneration, and to get about the patient will have to depend upon an apparatus, but this is better than death. [In the Prague Clinic Funke[3] studied 664 cases of osteomyelitis. The most frequent assigned causes were traumatism and cold. Only 56 of the patients were over 25 years of age. Funke believes that recurrent osteomyelitis means a new infection, and does not mean that organisms of the previous attack have remained latent in the part. Of the cases 37 were examples of multiple osteomyelitis. Funke says multiple osteomyelitis occurs only in young subjects, and chiefly in bones not completely developed.]

Neuber[4] writes of a method of treating **cavities in bone** which are left after the removal of sequestra or other operations. In all these cases he uses an emulsion of iodoform and starch. This mixture is made by taking 10 g. of wheat starch, mixing it with a very little cold water, and adding to it 200 g. of boiling 2% phenol-solution and 10 g. of iodoform, very thoroughly stirred. When this mass cools it is of the consistency of jelly, and will melt at the temperature of the room. This is introduced in the bone-cavity with excellent results. Neuber reports 22 cases, of which he obtained immediate union in 19. [Bone-cavities may be filled by means of decalcified bone chips (Senn), blood-clot (Schede), turning in skin and fastening it to bone with nails, formalin-gelatin (Schleich), bone-grafts, periosteal flaps, ivory, cement, celluloid,

[1] Lancet, Dec. 7, 1895. [2] St. Petersburg. med. Woch., 1895, No. 17, p. 151.
[3] Verhandl. der Deutsch. Gesellsch. f. Chir., XXIV. Kongress, 1895.
[4] Aerzt. Rund., Oct. 15, 1895, p. 657.

plaster of Paris, metals, a copper amalgam (Glück). Cavities after the removal of sequestra may be treated after the plan of Ercole. This consists in breaking down the lateral walls and making the upper and lower walls an inclined plane. The periosteum is preserved and sutured. The posterior portion only of the bone remains to give support. Barth has shown that after living bone has been transplanted it undergoes anemic necrosis and new live tissue takes its place; but the transplanted bone does not live. Dead bone is as useful as living bone in filling a defect, and so is bone which has had its animal matter destroyed by heat.]

Parsons[1] presents an elaborate study of **posttyphoid bone-lesions.** Attention was called to this subject particularly by the Toner lecture of 1876, in which Keen quoted 41 cases of bone-disease following continued fever, 37 of which cases had followed typhoid fever. With the identification of the bacillus of Eberth as the specific cause of typhoid fever has come a more careful study of the nature of these bone-lesions, with results which prove a relation between them and the primary typhoid attack. Some of them seem to be due purely to the bacillus of Eberth; others are associated with the action of pyogenic cocci. He reports 5 cases presenting different aspects of the condition, and in all but 1 of these cases the pure culture of the bacillus of Eberth was obtained. All but 1 of these cases demanded operations. Radical operation is usually necessary in order to remove all of the diseased area, and simple incision and drainage are rarely curative. This disease may arise a long time after the termination of the fever, from 10 to 18 months, and before the attack fully announces itself there may be a long period of quiescence. The symptoms are discussed by Parsons, and he tells us that they are at first more or less intermittent, and later become more positive and localized. The diagnosis of these cases rests largely upon the history of the previous typhoid fever. The occurrence during or after convalescence is suggestive purely of typhoid cases. The prognosis is good, as a rule.

INJURIES, DISEASES, AND DISLOCATIONS OF THE JOINTS.

INJURIES AND DISLOCATIONS.

Biddle, who has had an enormous experience with **sprains,** read a paper upon sprains and their treatment before the Alumni Association of Jefferson College. After a description of the nature and diagnosis of sprains, he considered the relative frequency of sprains in each articulation and discussed their treatment. In speaking of sprains of the vertebral column, he stated that when the symptoms are local, when there is neither paralysis nor sensory disturbance except at the point of injury, when the functions of the kidneys, bladder, and rectum are unimpaired, it is certain that the cord has escaped damage; but even if the cord has escaped damage, there might be extravasation of blood into the vertebral canal, inflammation of the fibrous structure about the meninges or cord, so leading to degenerative lesions in the cord itself. The best way to avoid such results is to insist upon absolute rest upon a hard

[1] Ann. of Surg., Nov., 1895.

mattress for from 4 to 6 weeks. In cervical sprains large sand-bags should be applied on each side of the head and neck and a low pillow is used. Pain is allayed by the administration of 10 gr. of Dover's powder every 3 or 4 hours, and in these cases he likewise administers 20 to 30 drops of fluid extract of ergot 3 to 4 times daily. In chronic cases rest and massage with chloral and compound soap liniment once a day, and small increasing doses of potassium iodid, will aid absorption. In dealing with a sprain of the joint of the extremity he applies oakum around the joint and puts the joint at rest by well-padded splints, thus securing rest and compression. He renews bandage twice a day if necessary, and allays pain and spasm in the beginning by the use of Dover's powder or morphin. If there is much swelling, he applies an elastic bandage over the oakum. As to the time the joint should be kept at rest, he has no special limit, but decides each case upon its necessities. If the joint remain too long unused, there is the possibility of its becoming ankylosed. If the joint be used too soon, there may be acute synovitis excited, which might destroy the joint. In these injuries he makes gentle yet firm passive motion in the direction of flexion and extension, usually on the third or fourth day, but avoids lateral movements in the ankle and knee-joint. If a chronic sprain comes to him, he gives the patient ether, breaks up the adhesions by forcible manipulations, and treats the case as a recent injury. In these chronic cases massage is invaluable. In a sprain of the knee-joint, if the effusion is not absorbed in a week or ten days, he aspirates and then makes firm compression. When the ligamentum patella is ruptured he treats the case with an apparatus, as in fracture of the patella.

Graham[1] strongly advocates the use of **massage in sprains,** bruises, and dislocations. The rubbing should begin in the healthy tissues and gradually enter into the injured area. The manipulator first gently strokes and then kneads, and after doing this for 15 or 20 minutes it will be found possible to use firm pressure in rubbing over the parts which were recently most tender. After rubbing a bandage is applied and these manipulations are repeated twice a day.

Freeman[2] reports a case of **spontaneous dislocation of the hip-joint in connection with typhoid fever.** He sets forth the following condition under which this may arise, reviews the literature of the subject, and tells us that the history of a typical case would be somewhat as follows: The child passes through a severe fever accompanied by swelling of the hip-joint. While still in bed or later on it is noticed that one of the patient's legs is shorter than the other, usually from $\frac{1}{2}$ to 2 in., and this is especially noticeable after the leg is flexed at the hip. The leg is held in a position of marked abduction and inversion, although, as Keen mentions, owing to the extreme relaxation of the parts about the joint, the limb may rarely assume other positions. In Freeman's case paralysis of both limbs occurred in the 4th week of the fever. This paralysis lasted 1, 2, or 3 days. At the end of the 4th and at the beginning of the 5th week pain and swelling occurred in

[1] Edinb. Med. Jour., Aug., 1895. [2] Med. News, Oct. 26, 1895.

the right hip, followed shortly by similar symptoms in the left hip. The child left its bed between 6 and 7 weeks, and then it was noticed that there was decided trouble with the left hip. The case resembled the third stage of coxalgia. He made an attempt to reduce this dislocation under ether. Reduction was accomplished, and as soon as the bone was replaced all the motions of the joint returned to normal. At the end of 10 weeks the child was able to walk fairly well, and at the end of 5 months the limb had markedly decreased, although stiffness of the joint was still present. Dislocation was, as is usual in these cases, on the dorsum of the ilium.

Roberts[1] reports a case of **congenital dislocation of the head of the humerus.** He considers the condition to be a malformation like to that which exists in the congenital dislocation of the hip. Reduction was out of the question by ordinary methods, and he has devised an operation which up to this time has been refused.

Phelps[2] reported a case of congenital subspinous dislocation of the head of the humerus. Phelps's opinion was that these cases should be treated by incision, and either putting the head of the bone back or performing resection to make the head fit in the old glenoid cavity. Phelps discovered in doing the operation that even extensive paring of the head of the bone did not permit of its restoration. He decided that the pectoralis major, teres major, and latissimus dorsi muscles had become agglutinated around the head of the bone. He feared to detach these muscles because of the likelihood of impairing the future usefulness of the arm. He therefore pared down the head of the bone until it was the size of the old glenoid cavity, and was then enabled to easily replace it in the socket by paring down the excessive amount of capsule and stitching it up behind the head of the bone.

Congenital dislocation of the hip was discussed at the Congress of Gynecology and Obstetrics in the fall of 1895.[3] Lannelongue presented records of 3 postmortem observations. In the first case it was found that the head of the femur had never departed from the acetabulum, but there was a malformation consisting in an enormous disproportion between the head of the femur and the cotyloid cavity; that is, the cavity had atrophied to a great extent, the atrophy forcing the caput femoris outside of the joint. In the second case the head of the femur was situated amongst the soft parts, not touching the iliac bone, while the fibrocartilaginous cotyloid ligament had been separated by the displacement of the head and remained as a collar around it. In the third case the acetabulum was found very much atrophied, whilst the head of the femur was its normal size. Lannelongue considers that this affection is caused by atrophy of the muscles of the thigh and acetabulum on the same side, and he thinks the original cause was in the nerve-centers of the spinal cord, the first lesion very probably being hydrops articuli.

Broca discussed the subject, and took issue with Verneuil that this form of dislocation is paralytic. The fact that the head of the bone is larger than the

[1] Ann. of Surg., Dec., 1895.

[2] Am. Med. Surg. Bull., Nov., 1895.

[3] Practitioner, Dec., 1895.

cavity shows, however, how useless are attempts to reduce the deformity by manipulating or to treat it by external maneuvers, extension or counter-extension. Broca thinks that there is no resource except operative treatment. He performed Hoffa's operation 28 times upon 25 patients. Hoffa's operation, it will be remembered, consists in gouging out a very large cavity from the ilium into which the head of the femur can be inserted. If the head of the femur is found too far away to be inserted, the only resource is resection of the hip. Calot remarked that the report of cases reduced without operation were almost invariably errors of diagnosis, although 4 well-established cases were undoubtedly upon record. Reduction of the head of the bone without operation is in almost all instances impossible.

Bennet[1] contributes a most useful paper upon **injuries of the thumb.** He discusses elaborately the dislocations of the metacarpo-phalangeal joint, and studies out elaborately a series of experiments. The paper will be of great value for reference.

Morton reports a case of that rare accident **dislocation of the carpus backward** in a boy of 16. He had fallen between two rails with his left arm backward and the hand pronated under him; the thumb hit the ground. In this case the symptoms were characteristic: the radial and ulnar processes were in the normal place and the carpus projected upward and backward. Reduction was easily effected by fixing the forearm, grasping the hand, and making forcible extension. A slight grating was felt. There was no radial fracture. Probably in this case when the fall came the principal weight was borne by the thumb-side of the hand, and thus the carpus was dragged backward.

McBurney[2] reports a case of **reduction of the humerus** complicated by fracture at the anatomical neck. He used the appliances which he devised, a description of which is given in the *Year-Book* for 1896. In his previous paper he had applied his method to the reduction of dislocations complicated by fracture, in which fracture took place at the surgical neck, and he had been apprehensive that in dealing with the anatomical neck it would be necessary to make a very large exposure of the joint, and that the hooks when inserted into the drill-holes in the small fragment of bone would be apt to tear away the cancellous structure; but in this case he effected reduction most satisfactorily.

Judd[3] reports a case of **luxation erecta** of the shoulder-joint. The patient, a man of 32 years, had fallen upon the floor, and as he fell grasped the edge of his desk; thus the arm was abducted, rotated inward, forward, and carried slightly backward. When the patient was first seen his left arm was upright, and the forearm was pronated and resting across the back of the head just below the occiput. The head of the humerus lay in the axilla just below the glenoid fossa. Reduction was easily effected under ether by traction upward and with manipulations over the head of the bone. Only 9 cases of

[1] Dublin Jour. Med. Sci., Dec. 2, 1895. [2] Ann. of Surg., May, 1896.
[3] N. Y. Med. Jour., Oct. 19, 1895.

this variety of dislocation are spoken of by Stimson in his treatise on dislocations.

Ward [1] presents an easy method for securing **reduction of dislocation of the humerus** in any variety of that dislocation. The patient is laid upon the floor; the arm is carried up by the side of the head; the surgeon holds the scapula down with one hand and presses the humerus into place with the other hand. After carrying the arm up by the side of the head, it may be well to give the hand to an assistant, while the surgeon has both hands free to pull down the scapula and to push up the head of the bone. Chloroform is never needed. [To fix the scapula and pull the arm above the head and make traction with the foot seem to be entirely similar in principle to Ward's plan. This method was used by Sir Astley Cooper, and was a favorite plan with the late Prof. Joseph Pancoast.]

Robinson [2] reports 3 cases of **acquired subluxation of the knee-joint** in young children. All the cases were in young females close on 12 months old, who had all been previously healthy and just getting on their feet; all suddenly, from some altered condition of health, perhaps associated with teething, got flaccidity of the muscles of the lower extremities and probably laxity of the ligaments, and with the advent of this loss of support the altered movements in the knee-joints were noticed. Rickets did not exist in either case, neither did infantile paralysis. The cases recovered with the use of simple internal remedies to restore the health and rubbing of the muscles of the leg to increase their bulk and tone.

Flower [3] reports a case of **dislocation of the femur upon the pubes,** and removal of the head of the bone by operation. The man labored under locomotor ataxia, and the head of the bone was broken from efforts at reduction. The head of the bone was removed through an incision, and 15 months after the operation the patient walked very well. [The most notable and original contribution upon the subject of dislocations is the Gross prize essay for 1895 by Dr. Oscar H. Allis. We are unable to abridge it, but strongly commend it to the reader's attention. It is a careful study founded upon elaborate experiment. It revolutionizes our views of dislocations. It is surgical philosophy, and will take rank with the studies of Malgaigne, Astley Cooper, and Bigelow. All surgeons should read it.]

Neuber of Kiel in treating **joint-tuberculosis and bone-tuberculosis** [4] makes an incision, removes all fragments and tubercular foci, fills the cavity with an emulsion of iodoform and glycerol of the strength of 10%, and sews up with buried sutures without drainage. [Several times recently we have tried this plan with success. In each case the joint was for a time stiff after operation, but became mobile under the influence of massage.]

Stoker [5] gives his experience of **excision of the knee-joint for tubercular disease.** He is an advocate for the operation of early excision in

[1] Med. Rec., Jan. 11, 1896.
[2] Brit. Med. Jour., July 27, 1895.
[3] Ibid., Nov. 2, 1895.
[4] Arch. f. kiln. Chir., Bd. xlix. Heft i., 1895.
[5] Practitioner, Feb., 1896.

tubercular arthritis. He does not intend to disparage other measures, such as tunnelling of the bones in the neighborhood of the joint or erasion of the interior of the joint, although the value of the latter procedure is questionable. Observation leads him to place a diminishing value upon erasion of the knee-joint.

He gives some statistical details of the last 30 consecutive cases in which he had operated. He secured 27 useful limbs, and all of these patients are well and active; 2 cases required subsequent amputation, but made good recoveries. There was only 1 death in the series, a boy who died of phthisis within 4 months of operation. The period of hospital detention subsequent to operation varied from 5 weeks to 8 months, the average being 4 months. There were only 2 cases in which suppuration did not occur. In the last 24 cases silver dowels were used to fasten the tibia to the femur. The surgeon should not be discouraged in these cases because sinuses remain for 1 or 2 years. They usually close before that date, but even after this they may frequently be cured, and erasion of sinuses is seldom necessary.

Stokes[1] has lately tried **Bier's treatment** in joint-tuberculosis. He is disposed to doubt its general value in the knee-joint. In 2 cases in which he excised the knee this method has been tried, but abandoned, and an operation made evident that the tubercular disease in the soft parts about the knee was in process of cure, but that the interior of the epiphyses show no reparative tendency. Some surgeons have asserted that the removal of the epiphyses of the femur or the tibia in early life is so grave a matter that excision is forbidden in those cases in which the extent of the disease renders it necessary to go beyond the developmental cartilage, because such a great degree of shortening will follow as to render the limb almost useless. His experience contradicts this statement. Nature seems in instances where the knee-epiphyses have suffered to provide compensatory growth in other parts of the engaged bones. But little shortening follows excision of the knee even at tender years.

Smith and Sturge[2] contribute a valuable article upon the **suppurative joint-lesions of scarlet fever.** They report carefully 9 cases, and then discuss the joints affected, the condition of the joints at the time of onset, the association of nephritis, the heart-conditions, the mode of onset, the source of infection, the treatment, and the results. They advise early and prompt incision and drainage, and besides this they lay stress on the advantage of prolonged immersion of the joint in a warm boric-acid bath. During the intervals between the baths hot boric fomentations are preferable to dry dressings. Nasal feeding is in some cases essential in order to combat the exhaustion of the patient, and may often be used as an easy way of giving extra food in cases when the patient is exhausted with the effort of taking nourishment by the mouth. Ankylosis need not necessarily occur even when suppuration has been profuse. In order to prevent this ankylosis, early passive movement should be adopted soon after the joint is opened, the arm being put

[1] Practitioner, Feb., 1896.

[2] Lancet, Nov. 16, 1895.

in a different position each time it is dressed. The article will well repay perusal.

Gamgee[1] calls attention to the fact that **synovitis** or **suppurative arthritis** may occur as a complication of **erysipelas.** In 817 cases of erysipelas one or the other of these conditions took place. The complication may arise at any time during the attack. The suppurative form requires the promptest and most heroic treatment. Disorganization of the joint will follow, or even the death of the patient, otherwise. The prognosis will depend on the same factors as in other cases of suppurative arthritis. The treatment is perfect rest of the joint; if suppuration exists, we make free incision after drainage, and then immobilize the parts. In some cases amputation will be found necessary.

Roux[2] discusses the subject of **chronic traumatic inflammation of the semilunar cartilages.** Its causes are most commonly squeezing, occasionally twists, and very rarely blows. This squeezing of the cartilage may take place when the knee is hyperextended, when the body is rotated with the leg extended and the point of the foot, which is the pivot, is suddenly arrested. It may occur when the person is in a crouching position and begins to make the movement of extension. It may also occur when the knee is rotated suddenly inward. In 90% of cases the internal cartilage is affected. Subsequently the cartilage becomes thickened from inflammation and the capsule of the joint subsequently involved. The thickening and painful mass can be found between the internal lateral ligament and the edge of the tendon of the patella. Roux says that rest will not cure the case. He advises the use of massage over the cartilage itself and over the quadriceps muscles.

Richardson[3] commends the value of the **diagnostic auscultation of joints.** The double stethoscope is the best instrument to employ, the mouthpiece being covered with rubber to avoid friction. In the healthy joint of a young person we will find no sign on movement, and even after the two ends of bone are brought against each other with force there will only be a very soft percussion sound as if two cushions were striking together. A very slight trouble in the joint gives origin to distinct sounds. He describes 5 joint-sounds—simple dry friction, dry grating, coarse grating, moist crepitant, and coarse crepitant. [We have always been troubled in our trials of this method by the scraping sounds caused by the contact of the instrument and the moving part. The rubber tip suggested by Richards may obviate this trouble.]

Marsh[4] discusses the pathology and clinical history of **joint-ankylosis.** He tells us that it used to be taught that the only manner in which a joint could recover after it had been involved in suppuration was by the development of bony ankylosis; that there was only one cause for bony ankylosis—namely, suppuration. We now know that neither of these propositions is correct. Suppuration is not necessarily followed by bony ankylosis. This is illustrated in pyemia, gout, suppurative arthritis following wounds, acute

[1] Birmingh. Med. Rev., 1895, vol. xxxviii. No. 205.
[2] Gaz. des Hôp., No. 125, 1895.
[3] Asclepiad, vol. xi. No. 43, p. 270.
[4] Brit. Med. Jour., Nov. 2, 1895.

arthritis in infants, and in other cases. In all these, if the joint concerned is freely opened, irrigated, and drained, free movement may be preserved. In some instances the mere aspiration of the pyemic joint may be followed by complete repair. Generally, however, in acute suppuration of the joint, unless there is free drainage, ankylosis will take place, but this ankylosis is rarely fibrous. There is no question that acute bony ankylosis is found following acute suppuration. In chronic suppurative conditions not only is bony ankylosis not the rule, it is the exception. Thus should ankylosis follow tuberculous disease of the hip or the knee, it is rarely bony and is commonly fibrous. Bony ankylosis often occurs in joints quite independent of suppuration, and it is this part of the subject that Marsh invites attention to—bony ankylosis in tuberculosis, in Charcot's disease, in nerve-injury, in gout, in gonorrheal rheumatism, in contusion of joints, in the spine in lateral curvature, and in osteoarthritis. Marsh says that bony ankylosis is sometimes reparative and is sometimes degenerative. When it occurs in acutely inflamed joints it is reparative. It is also reparative when it occurs in tuberculous disease of the joints or spine. In other cases bony ankylosis is a part of wide degenerative changes in the structure involved. It is degenerative in gout; it is degenerative in Charcot's disease. It must be termed degenerative also when it replaces the normal structures by a tissue which is inappropriate for the discharge of the functions of the part; for example, in ossification of the ligaments of the spine and of the joints and ligaments of the ribs. He enumerates 4 propositions: 1. Whenever this condition seems likely to occur the joint should be kept in a useful position; 2. We know of no means by which threatened bony ankylosis can be averted; 3. The use of passive movements cannot prevent bony ankylosis. Indeed, by maintaining irritation and promoting inflammatory exudation passive motions are likely to produce a directly opposite result; 4. When bony ankylosis has occurred, excision or osteotomy may be freely employed to correct any deformity that has taken place, for by modern methods that are now available these operations are attended with scarcely an appreciable risk.

VENEREAL DISEASES.

Heiman[1] contributes a paper, "A Clinical and Bacteriological Study of **the Gonococcus Neisser** in the Male Urethra and in the Vulvo-vaginal Tract of Children." He states that the most satisfactory medium for cultivating the gonococcus is chest-serum agar. Secretions taken from the normal urethra gave negative results so far as concerned the presence of the organism. Such secretions contained bacilli and various cocci, and even diplococci, but none of these organisms could be decolorized by Gram's test, thus differing from gonococci. In 16 cases of gonorrhea he showed that the urine was acid in 15 of them and was neutral in 1. He found that urine-agar was valuable for cultivation purposes, but not for transplantation. Another satisfactory culture medium is placental blood-serum. The best agent to stain with is a 2%

[1] Jour. Cutan. and Genito-urin. Dis., Sept., 1895.

alcoholic solution of methylene-violet. He examined the vulvo-vaginal tract in 20 normal children, and did not find in a single instance the gonococcus Neisser. The diplococci found in pus-cells which bore some resemblance to gonococci have been called pseudogonococci. Instead of this name, he suggests that they be known as diplococci found in the vulvo-vaginal tract of children. Whether these diplococci are pathognomonic of any infectious process he was unable to say, but he does know that they are constantly found in cases of colpitis and they cannot be decolorized by Gram's method.

Dr. Heiman then reviews the literature of vulvo-vaginitis in children. The causation in these cases is often very obscure, but occasionally a direct history of infection may be obtained. The way to stop the spread of vulvo-vaginitis is isolation. The most common mediums for carrying the poison are towels, clothing, instruments, etc. He divides the disease into two classes: 1. Catarrhal, due to uncleanliness, foreign bodies, or to traumatism or to nongonorrheal infection; 2. Gonorrheal vulvo-vaginitis, due either to a pure or mixed infection. The author then sets forth a number of inoculation experiments, and tells us that the crucial test for the gonococci is either inoculation in the human subject, although for obvious reasons this method has been seldom employed. The conclusions of the author are as follows:

The gonococcus Neisser is never present in the normal urethra.

The diplococcus found in the normal urethra can positively be differentiated from the gonococcus Neisser by Gram's test. The gonococcus which Turro described is not the gonococcus.

The best culture medium is liquid sterile chest-serum.

Gram's stain is the crucial test for the gonococci.

For ordinary staining purposes a 2% alcoholic solution of methyl-violet will answer.

The gonococcus is never found in the normal vulvo-vaginal tract.

The diplococcus found in catarrhal colpitis will not decolorize by Gram's method.

The gonococcus Neisser is found in cases of gonorrheal vulvo-vaginitis.

The inoculation-experiments made tend to confirm his belief in the specific power of the gonococcus.

Robinson [1] has tried **methylene-blue in urethritis,** and has decided that in the first day of the attack methylene-blue may do good by its action on the gonococci, but we run considerable risk of strangury and toxic effect. As soon as the gonococci have entered beneath the epithelial layer of the urethra, methylene-blue can do no good and can do no harm.

Hodara [2] advises the following methods of treating **gleet:** After the acute symptoms have subsided for some 2 or 3 months after the beginning of the disease, begin to dilate the urethra. Always make the distinction between an anterior and posterior urethritis. If an anterior urethritis is associated with a posterior urethritis, then the posterior urethra should be washed out with injec-

[1] N. Y. Med. Jour., Aug. 3, 1895.

[2] Ann. des mal. des organes genito-urin., Aug., 1895.

tions of silver nitrate 1 : 2000 to 1 : 3000. Dilatation is to be alternated with the injections. When we are treating a subacute case and find that 2 or 3 dilatations do not produce marked improvement, we may be sure that the case is going to be protracted. We should suspend dilatation for a month and substitute irrigation with silver nitrate, and then dilatation is recommenced. In chronic urethritis in which there is infiltration if dilatation produces increased discharge, it shows that there will be a rapid cure. Cases which are not cured by the above method must be treated through an endoscope. Catarrhal inflammation of the crypts of Morgagni is treated by electrolysis or the incision of the crypt orifices by small knives. Large spots of induration ought to be scarified.

Pucci[1] strongly advises the external use of **guaiacol in the treatment of orchitis.** He makes an ointment composed of 2 g. of guaiacol and 20 g. of vaselin, and paints this over the scrotum twice a day. Guaiacol produces a sensation of burning for about 10 minutes, but after this passes away the pain of the disease is very quickly modified.

Tuttle[2] has also used guaiacol in the treatment of epididymitis and orchitis, with great satisfaction. He applies it as follows: 10 minims of the drug are dropped into a butter-plate, and then painted along the line of the cord and the upper portion of the scrotum. This is left uncovered for half an hour, the parts being elevated. After this hot applications are applied. Tuttle's own method consists in laying the testicle upon the abdomen, covering it with a layer of flannel wet in hot water, and laying over this an ordinary English ice-bag filled with water as hot as the patient can bear.

Krisowski[3] points out **a sign of congenital syphilis** which has received but little attention. He describes a boy of 17 who came for advice with a sharp, infiltrated ulcer of the face. A number of lines were observed to radiate about the mouth. The upper incisor teeth and the corresponding portion of the jaw were absent and the hard palate showed three large scars. The tonsils, uvula, and pharyngopalatine arch were entirely absent, and the hard palate was united to the posterior pharyngeal wall by fibrous tissue. The epiglottis was swollen and the cartilages of Wrisberg and Santorini were absent. The septum of the nose was perforated. This union of the hard palate with the posterior pharyngeal wall almost never occurs except in hereditary syphilis. These linear radiating scars about the mouth are characteristic not only of congenital syphilis, but also of its early appearance. They enable us to distinguish early from late congenital syphilis, hereditary from the acquired form. [Hutchinson and Fournier have for many years insisted on the diagnostic importance of radiating scars about the mouth. The younger Gross always spoke of them in lecturing upon hereditary syphilis.]

Shillitoe[4] reports 18 cases of **indurated pseudochancres.** This condition is frequently called relapsing, and the term relapsing seems to imply recurrence in the original site. This is the usual course of things. But

[1] Gaz. d. Osped., June 1, 1895.
[2] Jour. Cutan. and Genito-urin. Dis., Oct., 1895.
[3] Berl. klin. Woch., Oct. 14, 1895.
[4] Lancet, May 30, 1896.

Hutchinson has told us that they occur to those who have had syphilis, and usually, too, not invariably upon the site of the former chancre. The example which Shillitoe quotes bears out Mr. Hutchinson's statements. Those cases in which secondary symptoms occurred after the appearance of the pseudochancre were all cases in which the pseudochancre appeared early in the disease—that is to say, within a few months of the primary infection—thus leading one to suppose that the presence of a pseudochancre influenced in no way the occurrence of secondary symptoms. Bumstead calls these lesions "recurrent indurations." To have called these new sores pseudochancres simply would seem to imply some relation to the soft or noncardinal symptom, induration; so he adopts the name indurated pseudochancres. He then gives the very interesting histories of 18 cases and discusses them in detail. He thinks that these lesions may possibly be considered as analogous to the relapsing inflammations of Paget. The author's observations show that the indurated chancre may appear at any interval after the initial lesion; that if the interval of immunity has been a long one, the indurated pseudochancre is not followed by secondary symptoms; that if the interval between the appearance of the pseudochancre and the original sore is a short one, the onset of secondary symptoms is not influenced in any way by the new sore; that these lesions may arise spontaneously quite apart from fresh intercourse; that if the history be not known, it is almost impossible to diagnose the pseudochancre from the initial lesion of syphilis; that the predominant secondary symptoms in the original syphilitic attack in the cases he has quoted were some affection of the mouth and throat rather than cutaneous eruptions; that the presence of induration in a sore, accompanied it may be by induration of the neighboring lymphatic glands, does not necessarily imply that the individual has been reinfected with syphilis; that these lesions yield rapidly to mercurial treatment or even spontaneously disappear; that these pseudochancres are not syphilitic, though occurring in individuls who are or have been the subjects of syphilis; that these lesions may eventually terminate in malignant disease. As Hutchinson has pointed out, "the knowledge of the facts as to recurring chancres is of very great importance, since without it very serious mistakes may occur, not only as regards treatment, but in reference to social and medico-legal questions."

Robinson[1] discusses **syphilitic joint-diseases in children.** He tells us that the effect of syphilis upon the joint-structures has received but scanty notice from writers on surgery. He has no doubt many cases which are now considered tuberculous and anomalous forms of rheumatoid arthritis are in reality syphilitic. In 1892, Hutchinson, Jr., delivered a very interesting address on this subject, and pointed out the different pathologic headings under which such cases should be grouped. With very trifling exceptions the same pathologic grouping holds good whether the cases are due to acquired or congenital syphilis. In this paper the writer refers only to the lesions met with in children. Congenital syphilis has one or two forms that belong to it alone.

[1] Brit. Med. Jour., May 16, 1896.

In older children it may be due to either the hereditary or acquired disease. In an experience of some years among children at the East London Hospital the writer has been struck with the frequency of acquired disease among them. Most of the cases were due to heredity. He advises the following classification of joint-diseases in children: 1. Epiphysitis of infants; 2. Symmetrical effusions, usually from 8 to 15 years of age. The two above forms are invariably congenital; 3. Osteitis (*a*) with simple effusion; (*b*) with gummatous infiltration of the synovial membrane and effusion; 4. Primary gummatous synovitis. These forms are met whether the disease be inherited or acquired.

DISEASES OF THE NERVOUS SYSTEM.

The **treatment of spina bifida** is the title of an article by Mayo Robson.[1] His operation consists in excision of the whole or part of the sac. He divides cases of spina bifida into 3 classes: 1. When the sac is so small that the case does not demand operation; 2. When operation is contraindicated by the fact that a very large part of the spinal column is fissured, or where the case is complicated by the existence of hydrocephalus or paraplegia; 3. In which the operation is indicated. He thinks the operation is indicated in meningocele whether the opening be large or small, in cases in which there are very thin coverings to the sac, in cases in which the cord is extended or nerves are spread out upon the sac-wall. [In some rare instances spontaneous cure follows rupture of the sac, but this accident usually causes death by giving ingress to organisms which cause septic meningitis. The same may be said of puncture performed without aseptic care. Until comparatively recently the favorite treatment was the plan devised by Morton of Glasgow—that was tapping, removing half of the fluid and injecting ʒj–ʒij of Morton's fluid (gr. x of iodine and gr. xxx of iodide of potassium in ℥j of glycerin), and painting over the puncture-hole with collodion. This method cured some cases, but it caused many sudden deaths. The modern operation of excision is a vastly better procedure, especially if associated with a closure of the bony cleft.]

Park[2] reports an interesting case of spina bifida in which he operated, closing the spinal gap by a celluloid plate. He excised the sac and pushed the ligated stump back into the canal. Into the opening in the spinal canal he fitted a thin piece of sterilized celluloid, so cut that he could spring its edges in under the bony margin. This case made a complete recovery. He tells us that this mode of operation is only applicable to those cases in which there is a relatively small bony defect. Robson has succeeded in a number of cases by transplanting periosteum into the defect, the periosteum being obtained from the bones of a rabbit and other animals. Osteoplastic operations have been performed by other operators, all of which are uncertain in result. Marcy[3] published a resume of the various methods of operating upon these cases. For the purpose of closing cranial defects both heteroplastic and autoplastic

[1] Ann. of Surg., xxii. No. 1, 1896. [2] Buffalo Med. Jour., Aug., 1895.
[3] Ann. of Surg., Mar., 1895.

methods have been described during many years. In 1820, Walther replaced a portion of a resected skull. In 1868, Wolff reimplanted bone in animals. Macewen and Weir then began to sew bone-fragments over the dura. In 1889, Seydel transplanted a portion of the tibia and the skull, and Poncet successfully implanted a portion of bone removed from the skull of a new-born infant dead of asphyxia. Hinterstoisser began to use celluloid plates, and Gerstein has successfully used rabbit-bone and ivory, aluminum, and other materials. Beach inserted gold between the pia and the dura to prevent adhesions at this point. A thicker specimen of the same metal might easily be used for the purpose of reinforcing or affording strength. The most serviceable material probably will be found in the future to be celluloid.

Wharton,[1] in reporting a case of **dislocation of the ulnar nerve at the elbow,** adds the report of 13 additional cases which he has found in literature. He tells us that this injury is extremely rare unassociated with fracture or dislocation, but that it may result from direct violence or from muscular effort or from violent flexion of the forearm, thus causing laceration of the fascia which holds the nerve in its groove. The symptoms of this injury are pain, tingling in the ulnar trajectory, and a certain amount of disability of the elbow, but the symptoms usually abate with considerable rapidity, and permanent disability rarely ensues. In some few instances neuritis develops, and in view of this possibility it is wise to replace the nerve by operation. Fixation of the elbow by plaster of Paris, the forearm being extended, will keep the nerve in place. This apparatus can only be employed for a limited time. The use of a splint to fix the arm at the elbow and a compress over the nerve have not been satisfactory, as the dislocation has generally returned after the removal of the dressings. The best method of treatment is that devised by MacCormick, who exposed the ulnar nerve, and, having made a bed for it by dividing the fibrous tissues behind the inner condyle, fixed it in its normal place by kangaroo-tendon loops passed through the inner margin of the triceps and loosely around the nerve. The divided margin of the fascial expansion of the triceps tendon superficial was sutured to the nerve. In Wharton's case no operation was performed, because the discomfort was slight, and he soon regained the use of the arm.

Wharton Sinkler[2] reports a case of **complete division of the musculospiral nerve,** in which Keen performed a successful suturing operation 3 months after the accident. It was 5 months after the operation before signs of an improvement were manifest, and some time after this function was restored. [This case proves that in many supposed hopeless conditions operation can be done with at least a fair chance of success.]

Park[3] considers the results of **division or resection** in the neck **of the pneumogastric and phrenic nerves.** The old idea of surgery was that such injuries were necessarily fatal. Park shows that in 15 cases in which the pneumogastric was involved in malignant disease or accidental injury 11 died

[1] Am. Jour. Med. Sci., Oct., 1895.

[2] Therap. Gaz., July, 1895.

[3] Ann. of Surg., Aug., 1895.

and 2 recovered, while in 2 instances the result has not been noted. In a total of 50 cases of accidental injury of the pneumogastric nerve we do not know the result in 2 instances, while of the remaining 48, 21 died and 27 recovered. Even in the fatal cases it is impossible to say that in any instance death was due to injury of the nerve, and some of the deaths occurred at such an early period that a nerve cause is extremely doubtful. The weight of the evidence is in favor of the comparative safety of attacking this nerve when involved in disease, and when too much other operating is not necessitated by the condition which caused the operative attack.

Guinard[1] is inclined to advocate the **resection of Meckel's ganglion for neuralgia,** instead of the removal of the Gasserian ganglion. Three cases of the former operation had been free from pain for over 2 years. Chalot considers the removal of the Gasserian ganglion a very dangerous procedure.

Krönlein[2] has operated for neuralgia twice by what he designates **the retrobuccal method** of exposing the third branch of the trigeminus. The operation is a safe one. It is easily performed, and it does not interfere with the functions of the part, but a fine scar is left on the cheek, and neither the masticatory muscles, Steno's duct, nor the facial nerve need be injured. In the second case he operated on he removed the superior maxillary nerve, even its intracranial portion, through the Gasserian ganglion, and even a portion of the ganglion. Both of these operations led him to think it possible to remove the fifth nerve from its intracranial course by an entirely extracranial operation.

Krause[3] has during the past 3 years advised the **removal of the Gasserian ganglion** and its posterior root by intracranial operation for the cure of severe neuralgia. Resection of one branch or of more than one branch of the fifth nerve produces no certain result, and we know that in facial neuralgia the Gasserian ganglion has undergone pronounced change. Krause makes an osteoplastic flap, the base of this flap being just above the zygoma, and he cuts the bone with a circular saw which is run by electricity or by an ordinary dental engine. The dura mater is carefully detached from the bone of the middle cranial fossa, and elevated, together with the brain, by a broad retractor. The middle meningeal artery is now tied and divided near the foramen spinosum. The inferior maxillary and the superior maxillary branches are found, exposed, and cut through at the foramen rotundum and foramen ovale, the ganglion and its posterior root after being isolated are twisted out. In 3 cases Krause was able to extract the posterior root as far as the pons Varolii. The first branch is attached to the wall of the cavernous sinus. We make no attempt to expose it with a knife and tear it across when we remove it. The flap of skin, muscle, and bone is replaced.

Krause says that the average period of the after-treatment is 2 weeks. He prefers this operation to Rose's because the latter does not satisfactorily expose the ganglion, and in consequence we cannot be sure that the ganglion has been entirely removed. Rose's operation, too, opens us to the danger of injuring the

[1] Gaz. des Hôp., 1895, p. 1251. [2] Beit. zur klin. Chir., xiv. No. 3, p. 725.
[3] Centralbl. f. Chir., 27, 1895.

Eustachian tube and setting up a septic meningitis. The greatest danger of the operation is hemorrhage, because we may cut the meningeal artery before we have tied it or we may injure the cavernous sinus. In some cases because of the degree of hemorrhage it has been necessary to perform the operation in two stages. The pressure made upon the brain by lifting it with the retractor does not seem to produce any bad effect. Of 51 of these operations upon record, 5 were fatal; not a single case of relapse has yet been announced. Krause has never seen any serious injury of the eye follow the operation, although there is always anesthesia of the cornea and the conjunctiva. Keen[1] has reviewed this subject and reported **5 additional cases.** He then announced and still maintains the belief that the Hartley-Krause method is much superior to Rose's operation, because the mortality is less, because access is had to the ganglion through a large opening, and because we are enabled to remove the entire ganglion with its roots. An osteoplastic flap should be cut with chisels or a circular saw. There will always be hemorrhage on trimming down the bone, the source of the hemorrhage being the anterior branches of the middle meningeal and occasionally the main trunk. In 3 of Keen's cases the posterior branch of the middle meningeal was also injured. In 3 cases the main trunk was torn. Bleeding from the branches can be controlled by encircling the artery with a fine silk thread and tying, the thread being passed under the artery by means of a curved Hagedorn needle. In bleeding from the main trunk plug the foramen spinosum with a curved blunt instrument (Allis's dissector), substitute the left fore finger for the dissector, and then pack under the finger with iodoform-gauze. The gauze is left in place for 3 days. Fowler's advice to ligate the external carotid as a preliminary procedure is bad advice, as such an operation is unnecessary.

The temporosphenoidal lobe is lifted from the middle fossa by the fore finger, and is held up by a broad spatula. When the bleeding from the middle fossa is very severe it may be advisable to do the operation in stages, packing with gauze to control bleeding, and 3 days later opening the wound, removing the gauze, and completing the operation. It is of course much better to do the operation in one stage if possible, as the danger of infection is vastly greater in a second operation than in the first. After isolating the ganglion and its 2d and 3d divisions from the dura above and the dura beneath, seize the ganglion with a pair of hemostatic forceps, cut the 2d and 3d divisions at their foramina, rotate the forceps, and thus avulse the ganglion and its roots. The first division must not be meddled with, because it penetrates the cavernous sinus, but the ganglion is torn off from this division. In Keen's first 4 cases the lids were not stitched together, and yet no trouble arose in the cornea. In the fifth case the eyeball was protected for 4 days by occlusive dressing, but nevertheless a corneal ulcer formed shortly after the operation. Keen suspected that the lids were open under the dressing, and that the anesthetic cornea was abraded without the patient's knowledge. In the sixth case the lids were stitched. After 4 days the stitches were cut, and the cornea was found in good

[1] Am. Jour. Med. Sci., Jan., 1896.

condition, but 24 hours later a corneal ulcer began to form. Dr. de Schweinitz freshened the middle of the lid edges and stitched them, thus occluding the middle of the palpebral slit, but leaving the ends open for the drainage of secretions.

Experiments on animals would indicate that the corneal trouble is not caused by microorganisms, but is caused by drying of the cornea and unnoticed injury of this anesthetic region, the remedy being a moist atmosphere (V. Hippel). Keen decided in future to close the lids after these operations, either by sutures or by adhesive plaster.

It is not absolutely certain that breaking up of the ganglion is insufficient for cure. The entire removal of the ganglion is not more dangerous to life, but is more dangerous to the eye. If time shows that breaking up the ganglion gives a permanent cure, that is the operation to be preferred. In the light of several reports of relapses after breaking up of the ganglion, it seems likely that removal of the ganglion is necessary. The mortality by Rose's method is 18%, by the Hartley-Krause method, 9.8%.

[Doyen of Rheims makes a sickle-shaped incision in the temporal region. The handle of the sickle is vertical, is between the external angular process and the auditory meatus, and passes not more than 15 mm. below the zygomatic arch. He then resects the zygomatic arch, sections the coronoid process of the lower jaw, and clears the temporal fossa. He finds the lingual and inferior dental nerves, clamps them, cuts them, and ligates the internal maxillary artery. He traces up the inferior maxillary nerve to its point of emergence from the foramen ovale. He then trephines the skull on the temporosphenoidal suture, and makes clear a large space by the surgeon. The base of the greater wing of the sphenoid is removed up to the oval foramen. By drawing upon the dental and lingual nerves the inferior maxillary nerve is brought clearly into view, and by traction upon the inferior maxillary nerve the ganglion and its branches are brought within easy reach. The superior maxillary division is cut at the foramen rotundum, and the ophthalmic division is cut at the sphenoidal fissure.[1]]

Mayo Robson[2] advocates the **treatment of meningocele** by a plastic operation. There is only one difficulty in operating upon a cranial meningocele, and that is that portions of the nerve centers may be contained in the sac; but this may usually be diagnosed by careful palpation with or without a preliminary aspiration of the sac. Even when uncertain, we are not prevented from doing an exploratory operation, for we can make an incision near the base of the tumor just large enough to admit the finger, and if it is deemed unwise to proceed, this incision can be readily closed. In simple meningocele there is usually a distinct neck to the sac, which neck should be ligatured off. The skin-flaps are then sutured separately, and the ligatured neck of the sac lies outside of the line of the superficial sutures.

Plummer[3] presents an elaborate research upon the surgical anatomy of the

[1] See Arch. provin. de Chir., vol. iv. No. 7, July, 1895; or the most excellent resume by H. P. De Forest in the Ann. of Surg. for Jan., 1896.

[2] Am. Jour. Med. Sci., Sept., 1895.

[3] Ann. of Surg., May, 1896.

middle meningeal artery. He shows that this artery is subject to wide variations in course and distribution. After it leaves the foramen spinosum there is no location at which the main trunk or one of its terminal branches has a definite position and a constant position, except where the anterior branch crosses the sphenoparietal suture on to the anterior inferior angle of the parietal bone. A trephine opening 1 in. in diameter immediately back of any portion of the coronal suture will almost invariably reach the anterior branch or a branch from it. In the very great majority of instances also the trunk of the vessel is within the cranium. In some instances the anterior branch is derived from the orbital branch of the lachrymal branch of the ophthalmic. The chief supply of the parietal bone is from the posterior branch rather than from the anterior. The blood-supply of the dura mater traverses as many and as pronounced curves as that of the pia mater. In most cases the blood-supply of the skull is symmetrically arranged, but there are many exceptions to the rule. In the majority of cases the anterior branch is enclosed in a canal at the anterior inferior angle of the parietal bone. In locating the anterior branch the most advantageous site is that which reaches it high enough to prevent it escaping in case it originates from the orbital branch, and to expose or lie above the orbital branch when it exists merely as a communicating branch, and which involves least frequently the bony canal and the ridge along the lower end of the coronal suture.

Krönlein's method is the best on locating the anterior branch. No method will certainly locate the posterior branch. In seeking for the anterior branch we must avoid the region of the lateral sinus. The posterior branch is best located by Steiner's method. The ideal method for exposing the middle meningeal and its branches is by the Hartley-Krause osteoplastic flap. An essential step in the performance of Rose's operation is the shutting off of the circulation of the middle meningeal extracranially.

Cale[1] reports 2 successful operations for **traumatic insanity,** which he considers is rather an infrequent occurrence, but which is occasionally met with. He thinks that chronic meningitis and encephalitis play an important role in the production of insanity, and that this mental condition not unusually follows circumscribed inflammation of the vault of the skull. All injuries of the head work either as sole or contributing causes of insanity, and injury of the bones makes resulting insanity more probable than the injury to the soft parts. The insanity often arises during or shortly after the healing of a wound. Exostosis, tumors, or caries of the skull may be responsible for the condition. He then discusses the symptoms of the disorder and presents 2 cases. [Traumatic insanity is a rare condition. Occasionally an insanity follows an accident because of nervous shock, rather than physical brain injury. The true insanities have no demonstrable lesion, the disorder being in the subtle chemistry of the nerve-cells, and the surgeon's knife cannot correct aberration in tissue chemistry. Many and various lesions have been described, but they are secondary to the insanity, and not causative of it, and to remove a secondary

[1] N. Y. Med. Jour., Oct. 12, 1896.

lesion cannot cure the case. The subject has been obscured by ridiculous statistics, by faulty observations, by reporting cases under such absurd titles as delirium of persecution, and by failing to regard the effect of the operation per se. We are not justified in operating without clear evidence of local lesion. Let those who claim so much for the procedure report an authenticated case of cure of a man with a systematized delusion of persecution, and we will listen with attention. Many of those reported cured never were insane; others are still insane; others had only hysteria or hypochondria or shifting hypochondriacal delusions. A person who claims that by operation he "will empty the asylums," either means to empty them by increasing the death-rate or will not empty them at all. In fact, we would rather fear that the mental attitude of the surgeon indicated a probable though slight increase in the insane-asylum population of the near future.]

Horsley[1] reports 5 cases of **leontiasis ossium,** the term by which is meant the development of a bony new formation resembling an overgrowth of diploe, and attacking the cranial bones and by preference the frontal or more rarely the facial bones, especially the jaw. In 3 of the cases operation was performed and was successful. The operation consisted in removing the mass piecemeal from the border of conjunction with the healthy bone. In each of the 5 cases the growth commenced in childhood or in very early adult life. This condition caused considerable pain, owing to pressure upon the fifth nerve, and neither syphilis nor trauma was the exciting cause. In the portions which were subjected to microscopic examination it was found that there was an outer hard portion of bone which was formed of normal bony trabeculæ which were separated by enormous medullary spaces, these spaces being filled with connective tissue which is almost myxomatous in character. The central soft parts crumble very easily, and it is noticed that the bone trabeculæ are undergoing absorption, and that the medullary tissue is replaced by fibrous tissue.

Kramer[2] makes a contribution to the study of **cerebral concussion,** and he concludes that a blow to the head produces a momentary increase of intracranial tension, and consequently compresses the whole brain. Compression interferes with the blood-supply of the entire brain, and this interference accounts for primary symptoms. Syncopic death is produced by paralysis of the respiratory centers, the cardiac centers remaining intact, and the fatal result may often be prevented by the prompt employment of artificial respiration.

Von Bergmann[3] in an elaborate article upon **Advances in Brain-surgery** does not think that operative treatment is of much value in Jacksonian epilepsy. It is quite true that excision of the cortical area may stop attacks for a time, but they will return in the future. Cases of epilepsy due to tumors of the cortex may be cured by operation. He believes in opening the skull by means of a circular saw which is run by electricity, and by closing the resulting brain-defect. The greatest advance that has been made is in the technic of operating for the treatment of intracranial suppuration and for sinus-thrombosis. The operation ought always to be carried out in such a

[1] Practitioner, July, 1895. [2] Ann. of Surg., Feb., 1896. [3] Ibid., Mar., 1896.

manner that the first depot reached will be the site of the earliest mischief, and if we determine whether that condition has gone on to intracranial abscess, then the operation can from here be pursued in the regular course. In other words, the operation ought first to expose the roof of the cavity of the tympanum. Very great advances have been made in the treatment of infected sinus-thrombosis. Jansen has reported 20 cases successfully operated upon in the University of Berlin. In 14 of these cases there was a large abscess around the sinus, and in 11 of these there were extradural abscesses of the middle fossa. In 13 of Jansen's cases 6 were cured; in 17 of Macewen's cases 13 were cured; and in 13 of other operations 8 were cured.

Ashhurst[1] remarks upon **trephining of the cranium,** reporting 24 primary operations for compound fractures, with 11 recoveries; 2 were operations during the intermediate period, both successful; 3 were secondary operations, and 1 recovered, and 2 deaths, both in cases of abscess. He does not think that there is as much urgency in operating upon compound fractures of the skull as there is in the case of compound fractures in the extremities. In the latter the operation should be done as soon as the patient is able to bear it, but in compound fracture of the skull we find a larger number of recoveries in delayed operation than when the operation has been done immediately. Of course in bad cases, when the operation is evidently necessary, he does not advise delay. He has operated in 3 cases for syphilitic disease, with 2 deaths. He has been induced to trephine in 3 cases of epilepsy; all recovered from the operation; 1 was much benefited as long as he remained under observation; in the other 2 there was no evident improvement. In melancholia following an old fracture of the skull he trephined, but obtained no relief. He operated in 2 cases for convulsions which followed old injury; 1 died, and in the other there was no permanent gain. He has operated unsuccessfully upon 3 patients for cerebral complications resulting from middle-ear disease. Although he operated in 21 fatal cases, in only 1 case did the operation seem to be responsible for the patient's death. In regard to the locality of the injury, he finds that fractures involving the frontal bone, omitting those simply involving the frontal sinuses, there were 5, with 4 recoveries and 1 death. These figures do not confirm the general impression that there is special danger in fractures of the frontal bone. In cases of impacted fracture he does not believe in interfering in the absence of symptoms. In regard to watery discharge from the ear he has observed that so long as the discharge continues the patient may do well, but if it suddenly stops the patient will probably become comatose and die in a few hours. He has never seen a fracture of the base of the skull in which he thought trephining indicated. He thinks that an attempt should be made to prevent infection by cleansing the ears and, as far as possible, the nasal and buccal cavities. After securing cleanliness we will obtain recovery in a considerable number of cases, relying upon the use of Dover's powder, with hygienic treatment, rest in bed, cold to the head, laxative enemata, etc.

Bromet and Pardoe[2] record an extremely interesting case of **fracture of**

[1] Internat. Med. Mag., July, 1895.

[2] Lancet, Sept. 21, 1895.

the skull in which no history of injury could be obtained—in fact, with a history that on the very morning of the seizure he was apparently well, yet he passed into a drowsy and irritable condition, and subsequently into profound coma. He was a police sergeant, and had been seen by many people the night before this condition. He had gone to bed on Saturday morning, and had got out of bed for different purposes on several occasions. Later in the day his symptoms began. On Sunday night he was taken to the hospital. He lay on his side with closed eyes and breathed easily, but resented any attempt at examination, and made incoherent answers when roused by shouting in his ear. The pupils were normal and equal; the pulse was 56, full and strong. There was no paralysis; the lungs and the heart and other organs were apparently healthy. A bruise was noticed upon the left ear and another at the inner canthus of the left eye. The urine showed a specific gravity of 1030; it contained sugar, but no albumin. The next day the patient was quite unconscious, although there was no paresis. A consultation was held to decide whether the symptoms were postepileptic or diabetic, and it was decided to make an exploratory operation. Bidwell operated, and he found an extensive fracture extending from the center of the lambdoidal suture behind to the posterior part of the zygoma in front, traversing the occipital squamous portion of the temporal and parietal bones and also part of the zygoma. The fracture was fissured and splintered. Mr. Bidwell removed the splintered portion of bone, together with some more bone around it, in the neighborhood of the middle meningeal artery, and on opening the dura mater a large amount of lacerated brain-substance and fluid matter escaped. The blood was from one of the posterior branches of the middle meningeal. The wound was closed, and the patient for a short time appeared to improve, but in a few hours paresis set in upon the right side. The urine was now collected, and was found to contain not only sugar, but acetone. He died about 36 hours after admission. Postmortem disclosed most extensive fracture of the skull.

Miles[1] discusses the **diagnostic value of fluid discharges from the ear** and head-injury. He concludes that in most cases in which bleeding and welling of cerebrospinal fluid from the ear are present there is fracture of the middle fossa of the skull, but that these sinuses are not absolutely pathognomonic—that the fracture in many or in most cases is simply a coincidence. The great bulk of the hemorrhage comes from the vessels of the arachnoid and pia mater, and from the arachnopial membrane and the temporosphenoidal lobe of the brain, and not from the fractured bone; that the path of the discharge is along the sheath of the auditory nerve, through the lamina cribrosa to the vestibule, thence through the middle ear and ruptured membrane to the external meatus. Excluding the extraordinary risk of sepsis, the prognosis is better when these discharges exist than when they do not.

Estes[2] reports a case in which he used **gold-foil to plug a cavity** in the cerebrum, and 2 other cases in which he used it to replace destroyed dura mater, and thus retained the obturator function of the lost membrane. He

[1] Edinb. Med. Jour., Nov., 1895. [2] Jour. Am. Med. Assoc., Apr. 4, 1896.

considers a valuable adjunct to the use of gold-foil inside the cranium is its inhibitory action upon the growth of microorganisms.

Dana[1] discusses the operation of **craniectomy for idiocy,** and he thinks that good results may come from it. In his own practice he has had 12 cases, of which 3 died; in 1 there was doubtful result, and 3 improved. In considering statistics of 22 cases he says that 6 were improved and that 6 died. The type that offers the most hope from an operation is congenital idiocy not due to paralysis or epilepsy, the form of the condition which is most frequently associated with imbeciles. There may be ossifications of the sutures, but he does not think that the idiocy results from this. There may be some benefit due to the division of the skull and the relief of the intracranial pressure, but the chief value is that the operation calls personal attention to the general care, and the attention which is given acts beneficially on the mental condition. The period when operation should be done is before 4 years of age, although alleged cures have been reported up to the age of 9. We should not operate in cases of cretinism or inherited syphilis, and if the child has rickets it ought to be treated carefully before operation. Tubercular children ought not to be touched. Dana thinks we have a right to employ the operation upon carefully selected cases. [The number of cases in which operation should be attempted is very limited. This procedure has been practised so ignorantly and indiscriminately that it has become almost a reproach to surgery. Our views expressed in the *Year-Book* for 1896 remain unaltered.]

Sheild[2] advises us to treat severe **mastoid disease** by the implantation of skin-flaps (Fig. 75). The idea of implanting flaps of skin into the cavities left by the removal of a diseased portion was derived from the expression of Macewen, who spoke of "papering" cavities with skin, and it was partly derived from observing the remarkable manner in which the integument grows downward and fills up carious cavities in the long bones after the removal of sequestrum. In each of these 3 cases of Sheild it will be observed that they were chronic and inveterate disease — that previous operations had been performed which had failed to cure. After the operation now to be described such great improvement took place that it brought them as near to definite cure as could in the nature of things be expected. The operation is performed as follows: A flap of integument is raised from behind the auricle, which flap includes the orifice of any sinus. The flap is left attached by a stalk. The auricle is detached forward, and the soft parts are turned back over the mastoid by hori-

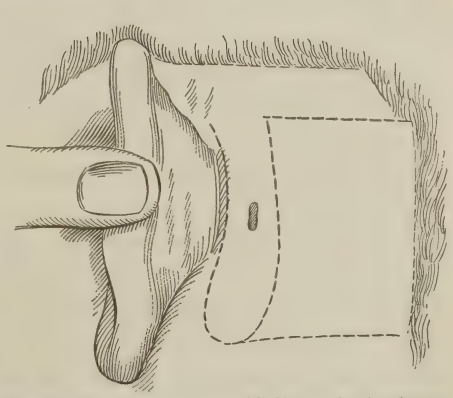

FIG. 75.—Treatment of mastoid disease by implantation of skin-flap (Lancet, Feb. 8, 1896).

[1] Am. Jour. Med. Sci., Jan., 1896.

[2] Lancet, Feb. 8, 1896.

zontal incisions. The lining membrane of the canal is separated from the bone. A ½ in. trephine is applied immediately behind the canal, or, if a sinus exists, this is enlarged with a gouge. The diseased bone is removed and caseous areas are scraped away. The overhanging edges are smoothed down with a chisel, and the posterior bony wall which separates it from the cavity just made is cut away with bone-forceps. Granulations in the tympanum are removed by the curet, and the tympanum and the mastoid are thrown into a common chasm. Chisels and gouges may be used to remove the bone, and a burr may be used instead of the two former. The flap of skin is pressed down into the cavity and is packed superficially with iodoform-gauze. In his first 2 cases he united the margins of the tunnel from the implanted flap, leaving an aperture for the gauze to be withdrawn. In the last case he left the tunnel entirely open, and believes that the latter plan is the best, as the discharge can be easily washed away and there is no chance for its reaccumulation.

Souchon[1] writes an article upon the **exploration of the brain with a needle** and syringe through capillary holes drilled through the skull. He drew the attention of the profession to this in 1889, and proposed this method to take the place of trephining: the simplicity of the procedure and safety recommend it as an easy means within the reach of a greater number than the more serious and complicated operation. He endeavored to determine the danger of operations upon dogs, and decided that it was possible and practicable to explore the brain in this manner. Matas has tried it upon a case, the result of which, however, was negative. He does not think there is the slightest danger of hemorrhage in this procedure. In August, 1893, Schmidt published a case where this process was used with a negative result, but this negative result was valuable in a diagnostic point of view. The idea was originally suggested by Middeldorf in 1856, and was repeated by Maas in 1869. [The procedure is both unsafe and valueless. If it shows nothing, we must trephine to reach a conclusion. If it shows something, we must trephine anyhow. The danger it exposes the patient to is hemorrhage. It should never be used.]

Starr[2] makes a contribution to **brain-surgery** with especial reference to **brain-tumors.** In speaking of cortical epilepsy he says that experience seems to show that, though a cessation of attacks may follow operations, these attacks are almost certain to occur in the future. He is becoming more and more reluctant even in well-defined cortical epilepsy, whether of traumatic or spontaneous origin, to advise operation. In cases in which the brain has been injured and there is an irritation cicatrix, the excision of this cicatrix will be followed by the production of another cicatrix and no permanent cure is effected. Experience of the last 3 years confirms the view he set forth in his book, that only 7% of brain-tumors are operable. The difficulties met with are first the troubles in localizing, and second the difficulty of reaching the tumor even when localized. Many surgeons have directly advocated trephining in every case diagnosed of brain-tumor as important, even when there is no

[1] Jour. Am. Med. Assoc., May 30, 1896. [2] Med. Rec., Feb. 1, 1896.

possibility of removing the tumor. This operation relieves intracranial pressure, and thus relieves headache and vomiting, vertigo, and optic neuritis. Horsley is a strong believer in this procedure, and he thinks that it even has a beneficial effect upon the growth of the tumor, occasionally producing its absorption. Starr thinks this operation is occasionally justifiable. It is to be remembered also that a marked change in the circulation consequent upon the relief of intracranial pressure may aid the absorption power of some drugs, and it is not to be forgotten that cases of brain-tumor have occurred in which the diagnosis is absolutely certain, but which have recovered under the use of mercurial inunctions with large doses of iodid of potassium.

Starr then records a case that shows even in individuals where there is no history of syphilis medical treatment alone occasionally succeeds. He thinks trephining for the relief of pressure is perfectly justifiable. The essential preliminary to the operation for brain-tumor is accurate localization and a reasonable prospect of reaching it. The nature of the tumor itself is always a matter of uncertainty. In a case of Dr. McBurney's in which every symptom pointed to a small tumor of the leg center of the right hemisphere operation disclosed a most extensive glioma which occupied both central convolutions and extended inward as low as the face centers. It is only when the tumor is small, lies on the cortex, but does not invade it, and can be removed without serious damage, that the prognosis is really good. Starr gives a tabulated statement of the results of operations for brain-tumor, as follows: The total number of cases operated upon for brain-tumor was 162, of which cases 137 were cerebral and 25 cerebellar; in 48 cases the tumor was not found at the time of operation; in 5 cerebral and 2 cerebellar cases the tumor was found at the time of operation, but was not removed; in 72 cases (65 cerebral and 7 cerebellar) the tumor was removed and the patient recovered; and in 35 cases (28 cerebral and 7 cerebellar) the tumor was removed, but the patient died.

Looking over successful cases, it is evident that the most favorable cases for operation are those in which the tumor is in the motor region of the brain, producing first local spasm, then local paralysis, or in the speech-area of the brain, or in the vital area of the brain. In each of these regions localization is easy and the tumor can be readily reached and removed.

Starr then gives a tabulated statement of the variety of tumor removed, and the results, during the 3 years 1893 to 1896, as follows: Sarcoma, 15—10 recoveries, 5 deaths; glioma, 4—3 recoveries, 1 death; gliosarcoma, 2—both recoveries; cystic, 8—3 recoveries, 5 deaths; tubercular, 6—3 recoveries, 3 deaths; gumma, 3—1 recovery, 2 deaths; fibroma, 1—death; angioma, 1—recovery; variety of tumor not stated, 7—3 recoveries, 4 deaths: total number of cases operated upon, 47; recoveries, 26; deaths, 21.

The tumor most frequently removed is sarcoma, with the best prognosis. Cysts are easily removed, but subsequent results are less favorable. It is not sufficient to evacuate a cyst, but its wall must be removed. If we simply evacuate it, it will refill, and when we remove the wall we damage surrounding structures. In order to remove glioma extensive excision of the brain is necessary, and if glioma recurs it can be excised a second or even a third time. Tubercular tumors have been successfully removed from the brain. Krönlein collected 15 of such cases, 5 of which were followed by permanent cure. Von Bergmann objected to this operation because of the liability of recurrence. The question of operating for gumma is an open one. Many of these tumors can be absorbed by the use of antisyphilitic remedies, but very large ones, which do not yield to medicine, we should operate upon.

Starr then records a table of tumors successfully removed during the last 3 years, of tumors trephined for and found, not removed, and of tumors trephined for, but not found. [Year by year the mortality from these operations becomes less. The fact that in 30% of these cases no tumor was found is a reproach to our power of diagnosis.]

DISEASES OF THE SPINAL COLUMN AND SPINAL CORD.

Tubby[1] in a paper on the **treatment of abscess and Pott's disease** maintains that with quiescent areas aspiration is only suited to the small residual abscess which follows a previous operation, with the idea of obtaining primary union. Aspiration can also be applied to deep-seated abscesses which are in immediate contact with serous surfaces or with viscera. Cervical abscess should be opened on the side of the neck. Psoas and lumbar abscess should be treated by the radical plans of Barker and Treves, and this method is most likely to succeed if the bone-disease is stationary or is healing. In children the incision should never be made in or near the groin, and the use of a drainage-tube is dangerous because of the liability to septic infection and the danger of forming a persistent tubercular sinus. The lumbar incision is very valuable in a certain limited number of cases. Many cases of abscess are opened by an incision resembling that of Sir Astley Cooper for ligating the iliac artery. The possibility of removing large bony sequestra by incision down to the vertebral column is very doubtful, and in a great number of cases no such procedure is attempted, because the bone is simply diseased upon its surface. We should always attempt to dissect out the sac, although we will frequently fail in the attempt.

Müller[2] writes upon **Acute Osteomyelitis of the Spine,** a rare disease of which but few cases have been recorded. The author reports a case which was situated in the dorsal region. The pressure-symptoms came on with great suddenness, and Müller inferred that they were due to sudden edema of the cord. There were none of those antecedent symptoms of irritation which are common in tubercular processes.

In an elaborate paper upon acute primary osteomyelitis of the vertebræ

[1] Med. Press, Oct. 30, 1895. [2] Deutsch. Zeit. f. Chir., xli. No. 6.

Makins and Abbott[1] say that an acute infective osteomyelitis of the bones of the vertebral column is a disease rarely met with, and is often recognized only on the postmortem table. The disease is more common than has been assumed. The paper contains the record of 8 cases with postmortem notes: 2 of these cases have been previously published; 2 have been furnished by recent papers of Hahn and Müller, and 11 others have been found previously recorded. Thus they have collected 21 cases on which to found their opinions. The cases are described in detail. The frequency of the occurrence of this disease is uncertain, and reliable statistics can be obtained only in the future. Hahn, by employing the statistics of previous observers and by adding some additional cases, shows that in 661 cases of infective myelitis the long bones were the seat of disease in 610 instances, the short and flat bones in 51 instances; and among the 51 instances of disease of the short and flat bones there was 1 instance of vertebral disease. There is no fixed period of age. The cases here are between the ages of 23 days and 46 years. Any region of the spinal column may be affected, although the lumbar region seems to be the one most liable to trouble. In every case suppuration occurred, although in a varying extent, and the situation of the abscesses corresponded with the seat of primary disease and the portion of the vertebra affected. In disease of the body of the vertebræ the abscess was anterior, either postpharyngeal, mediastinal, psoas, or pelvic, while in implication of the neural arch the abscess was posterior. The abscess travels in both directions when the transverse process is affected. In 2 cases of this condition slight angular curvature was noted. Implication of the spinal cord and meninges may take place, and it seems likely that in the past osteomyelitis has been overlooked, and has been the real cause of a number of cases of so-called spontaneous acute meningitis or myelitis. In a large percentage of cases nerve-complications are the cause of death. The symptoms and course of acute infective osteomyelitis of the vertebræ differ in no essential particulars from those observed when the same disease attacks the bones of the limbs, but the local signs do present special characteristics and differ according to the segment of the spinal column affected, while the frequent implication of the cord and its coverings gives to the disease its chief interest and importance. The authors consider the special symptoms which belong to the special regions of the back—the symptoms dependent upon implication of the spinal cord, nerves, and meninges, the diagnosis, prognosis, and the treatment. The treatment is the same practically as that applied to the disease in any other region. The special points to be borne in mind are the necessity for rest for the spinal column, to be maintained by attention to the position of the patient, the early recognition and the prompt incision of abscess, and the removal of dead bone. The last point is especially important when the neural arch is affected, and if the disease extends the whole vertical depth of one side of the arch, the bone should always be removed to prevent pus gathering in the canal. The later treatment when the bodies are the seat of disease includes the application of a jacket.

[1] Ann. of Surg., May, 1896.

Faisst[1] writes on **fractures of the cervical vertebræ**—injuries of very great danger, and likely to cause death at once or in the course of a very short time; the higher up the fracture is situated the more dangerous it is. The author reports a case in which the 4th cervical vertebra had been fractured, and in which there was complete paralysis, sensory and motor, of upper and lower extremities, and yet recovery followed.

Horsley[2] has recently reported 7 cases in which **laminectomy** had been performed either for caries or for fracture. None of the patients died. In Case 1 there was complete paralysis of all 4 limbs due to caries of the atlas and the axis. Power reappeared slightly on the 6th day after laminectomy, and progressively increased, and the patient is now entirely well, except some wasting of the interossei. The 2d case was performed for caries of the 5th and 6th cervical vertebræ. The patient made an excellent recovery. Case 3 was caries of the lower cervical vertebræ. The legs were completely paralyzed, and so was the right arm. There was very little power in the left arm. Power began to return the 3d day after operation, but the return was temporary and little real progress was made. Case 4 was a fracture of the cervical vertebræ 8 months previous, and there was paralysis of all the limbs. Analgesia was also present, and this condition points always to an affection of the central gray matter of the cord. Laminectomy was done, the bone of the 5th and 6th cervical vertebræ removed, and a mass of fibrous tissue was dissected from the dura. The patient rapidly improved, and the only remaining defect was wasting of the interossei. Case 5 was a fracture of the 6th cervical vertebra received about a week before. Laminectomy was done upon the 4th, 5th, and 6th cervical vertebræ, and a ridge was removed which had been compressing the spinal cord. On the 12th day power began to return, and the patient completely recovered. Case 6 was a case of fracture of the cervical vertebræ with the gradual onset of paralysis. Laminectomy was done upon the 6th and 7th vertebræ, when a projecting ridge was felt, but on examination this disappeared. The patient is at present making a slow recovery. Case 7 resulted from a blow upon the head in which the patient walked for 200 yards, and then became with great rapidity completely paralyzed. From this condition he recovered with partial spastic paraplegia, with postaxial anesthesia of the upper limbs. Laminectomy was performed, the 6th and 7th cervical vertebræ were removed, and 3 weeks after the operation he began to recover, and made an absolute recovery.

Mr. Horsley tells us that in many cases after injury there is a transitory recovery, which is followed later by a return of the paralysis, this paralysis probably being due to edema of the cord. He thinks that when there is an absolute loss of the deep reflexes and complete vasomotor paralysis we must assume that there has been complete division of the cord. In the ordinary cases treatment by extension is applied for 6 or 8 weeks. In caries of the vertebræ laminectomy is always of service, because by its means we are able to

[1] Beiträge z. klin. Chir., xiv., 1896. [2] Lancet, Aug. 17, 1895.

remove thick masses which were making pressure upon the dura mater. In some cases operations are done because of impending asphyxia.

Page[1] in a clinical lecture on "Three Cases of **Fracture-dislocation of the Spine,** with Total Transverse Lesion of the Spinal Cord," discusses most instructively the leading facts which are known about such conditions, and presents an analysis of the chief features of his cases. In one of these cases the postmortem was of singular interest. The junction of the 7th and 8th dorsal vertebræ shows that there was a bend forward at an angle of 45°, the bend seemingly due to decrease in the depth of the body of the 8th vertebra; and it is evident that there had been a line of fracture of a very unusual kind. The right lower articular facet for the rib on the 7th vertebra was detached, and from this point a prominent ridge of callus ran downward and forward and inward to the 7th and 8th bodies. [This article will be found instructive in enabling us to determine whether or not a complete transverse lesion of the cord exists.]

GENITO-URINARY DISEASES.

DISEASES OF THE PENIS AND URETHRA.

Park[2] treated a **tough stricture** by a new method. He made a perineal section, having a filiform as a guide. To this filiform he tied a piece of fine braided silk, and drew the silk forward out of the urethra, and used it as a string saw, after the method of Abbey in dividing stricture of the esophagus.

Fenwick[3] reports a case of great interest. External urethrotomy was performed upon a patient with stricture and sinuses, but the tissues of the perineum were in such a bad state that the bladder could not be found. The bladder was subsequently opened by Cock's method. At a later time a portion of sheep's urethra was transplanted to make up for the loss between the posterior and penile urethra. A sheep's urethra was dissected out while the animal was under chloroform. The anterior end of the deep urethra and the posterior end of the penile urethra were freshened, and a groove was made between them. An elastic catheter was passed into the meatus, and was brought out at the perineal wound. The sheep's urethra was fitted over the catheter and brought up into the prepared groove, and the point of the catheter was pushed into the bladder. The graft was stitched into position, a drain was inserted, and the skin-wound was closed. The continuity of the urethra was entirely reestablished. [The fact that the graft adhered is an exception to the general rule that transplantations from animal to man fail to adhere.]

Fort[4] presents a strong argument in favor of **electrolysis in the treatment of stricture.** Fort's electrolyzer has the advantages of a urethrotome without its disadvantages. The instrument after introduction into the urethra is connected with the negative pole of a continuous-current battery; the

[1] Lancet, Feb. 8, 1896.

[3] Lancet, Feb. 8, 1896.
[4] N. Y. Med. Jour., Nov. 16, 1895.

positive pole is applied over the pubes or the front of the thigh, and the current is turned on. The operation is almost painless and lasts about 30 seconds. A current strength of 10 milliampères is used. There is rarely any bleeding, and the instrument does not heat. The urethra is asepticized before and after operation. Pass a sound the 3d day after operation, and another the 4th day, and the patient passes a No. 24 F. every month. The patient is not obliged to lay up after this operation. This process causes molecular destruction of the stricture. Some very hard strictures cannot be successfully treated by electrolysis. Fort has successfully applied electrolysis in the treatment of strictures of the rectum, uterus, urethra, and esophagus. [There seems to be no doubt that Fort has succeeded in applying electricity so as to cure stricture. Former attempts by others were failures, and sometimes made the stricture worse. The trouble seemed to be that any current sufficiently strong to disintegrate a stricture was certain to destroy a wide area of mucous membrane and leave the patient worse off than ever. Fort has unquestionably cured cases—cured them quickly and practically without pain and danger. This method will diminish the number of external urethrotomies, but will not completely do away with the employment of the latter operation in some cases.]

Weir[1] writes upon the **Treatment of Rupture of the Urethra** by Immediate Suture and Bladder Drainage. But few cases of suturing of ruptured urethra have been reported. Suturing is to be urged, though it does not of itself guarantee the patient against a subsequent stricture. The surgeon ought to get rid of the irritant effect of urine. This has usually been sought after by tying in a catheter, but urine is liable to get between the instrument and the urethra, and the retention of the catheter is apt to cause cystitis. Weir drains by suprapubic cystotomy associated with intermittent siphonic drainage. The posterior end of the divided urethra may be found by retrograde catheterization. If the perineal wound is douched for 5–10 minutes with a fine douche of hot water, and also vigorously rubbed with the fingertips, the urethra will become far more distinct. Weir uses Cathcart's apparatus as modified by Keen for drainage (p. 400). Weir reports 2 successful cases. He sutures the urethra with silk, sewing the roof first, then inserting a steel sound, and sewing the rest of the urethra about it. All the layers of the urethra are included in the sutures. There are 29 reported cases of immediate suture of the urethra, all of which were successful.

DISEASES OF THE BLADDER.

Daggett[2] describes a new method of **flushing the bladder and urethra,** which is superior to the plan devised by Feline. The patient is placed semirecumbent, the body at an angle of 45°, and the knees are drawn up. The nozzle is inserted in the meatus. This position favors the flow of fluid into the bladder, and so little force is required that it is only necessary to raise the elevator about 1 foot above the pelvis. When the bladder is filled the patient remains in the same attitude, and empties it by urination. This treat-

[1] Med. Rec., May 9, 1896.

[2] Buffalo Med. Jour., Oct., 1895.

ment is employed in cystitis. Patients with residual urine from enlarged prostate after a number of repetitions of the procedure often become able to entirely empty the bladder (bladder-gymnastics).

Clado[1] thinks that in a person with **enlargement of the prostate cystotomy** is indicated when catheterism is very difficult; when there is a bar at the neck of the bladder, producing partial retention which necessitates the retention of an instrument; when retention of an instrument is intolerable; when vesical paralysis exists; when cystitis, ureteritis, or pyelitis exists; when bleeding villous growths exist upon the bladder-wall.

Elliot[2] writes of **Suprapubic Cystotomy for Vesical Hemorrhage.** In rapid hemorrhage there are three dangers: Rupture of the bladder; obstruction of the orifices of the ureters; the hemorrhage itself. The indications are to perform suprapubic cystotomy, arrest the bleeding, and prevent obstruction of the ureters. If a tumor is found, it is removed; if there is a bleeding vessel, it is ligated; if a varicose vein is ruptured, we rely on pressure or the Paquelin cautery. If the bleeding comes from the posterior urethra, a piece of silk is tied to a soft catheter, the catheter is passed into the bladder by way of the urethra, a plug of iodoform-gauze is attached to the catheter, and the tampon is drawn into place by withdrawing the catheter. Elliot gives the record of a case in which he applied a loose tampon to the bladder.

Cathcart[3] has devised an **exhaustion-pump for siphonage of the bladder** after suprapubic cystotomy. By this apparatus the urine can be withdrawn as soon as it enters the bladder, and can be taken out through the wound or by way of the urethra. We require a pail, some rubber tube, a douche-pan, a Y- or T-glass tube, an S-glass tube, a screw clamp, and an L-shaped piece of glass tube to enter the bladder. The douche-can is filled with water, and is put on a higher level than the bed; the Y-tube is fastened with a safety-pin to the mattress, and the part below the Y hangs down over a pail upon the floor. The screw clamp is unscrewed just enough to permit the water to drop; this water collects in the S-tube, and as its tendency is to run out, it creates negative pressure in the other arm of the Y, to which is attached the tube which is inserted in the bladder. It thus draws urine from the bladder. When the urine and water accumulate to a certain degree in the S-tube there is a flow out and the liquid again accumulates (Fig. 76). [Keen has improved upon the apparatus of Cathcart (see Fig. 77). The change upon Cathcart's plan is "the substitution of the rubber tube, *C*, the glass tubes, *L*, *L*, *D*, and the loop, *E*, for Y- and S-shaped glass tubes, which cannot always be quickly obtained." Keen has devised a still further simplification. Instead of the screw *H*, a knot is tied in the rubber tube *B*. By tightening or relaxing the knot the flow of water is easily regulated.]

Dawbarn[4] has shown that the principle of **intermittent siphonage** was introduced long before the time of Cathcart by Dr. Swan, a dentist of Rochester, N. Y., and dentists have used it for a long period to keep the

[3] Brit. Med. Jour., Oct. 19, 1895.
[4] Med. Rec., May 30, 1896.

mouth free of saliva. Dawbarn has used a simple apparatus to obtain siphonage for 5 years. He uses only a fountain syringe with several additional feet of small rubber tubing. A clamp is placed upon the side of the tube. By this means the tube caliber is much lessened and fluid will flow in drops. *B* is the joint between the two pieces of tubing, but the connection had best be made by means of a T-tube. We may, if we prefer, cut a circle from the side of the exit tube, sew the end of the other tube to the edges of the opening, tighten the joint with rubber cement, and strap with adhesive plaster. The

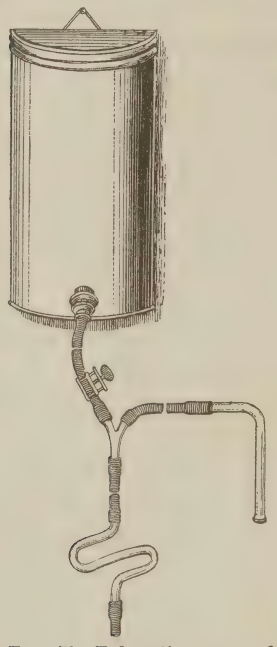

FIG. 76.—Exhaustion-pump for siphonage of the bladder (Cathcart, in Brit. Med. Jour., Oct. 19, 1895).

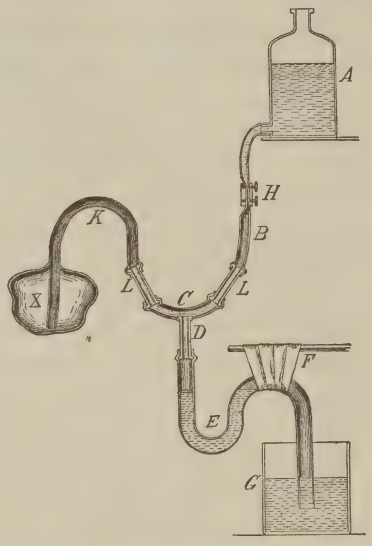

FIG. 77.—Keen's siphonage apparatus: *X*, cavity to be drained; *A*, reservoir; *K*, tube from cavity; *B*, tube from reservoir; *H*, clamp on tube from reservoir; *L*, *L*, *D*, glass tubes; *C*, rubber tube connecting cavity-drain with reservoir-drain; *E*, S-shaped rubber tube maintained in shape by hooking up at *F*; *G*, vessel containing antiseptic fluid.

exit tube is made into a trap by tying it into a loose knot. The water from the reservoir drops down into the trap and gradually fills it. When the trap becomes full, the fluid suddenly siphons off, and this rapid flow creates a vacuum above the trap, and urine is drawn into the tube to fill the vacuum. The process repeats itself at regular intervals. The fountain syringe only needs filling once in several hours.

Bloodgood[1] has devised a new apparatus to permanently **drain the bladder,** or to temporarily drain it, after the operation of suprapubic cystotomy (Fig. 78). The apparatus consists of a rubber bag reservoir. A thicker piece of rubber is sealed to the upper and central portion of the bag; this piece has a small central opening into which the head of the tube is inserted. The abdominal belt prevents dragging upon the bag. Two rubber tubes lead from the bag. The lower tube is to draw off the urine; the upper tube is to wash out the bag.

Briddon[2] reports the histories of 3 cases of **intraperitoneal rupture**

[1] Johns Hopkins Bull., Apr., 1896.

[2] Ann. of Surg., Dec., 1895.

of the bladder. In each case the rent was sutured, but in each case death ensued. Ten years ago Rivington presented a study of more than 300 cases, and in this list are only 2 well-authenticated cases of recovery. In only 1 of these cases was the rent sutured. The proper course in intraperitoneal rupture is to perform celiotomy, close the rent with silk sutures, irrigate the peritoneal cavity with hot sterile water, sew up the upper end of the incision in the belly-

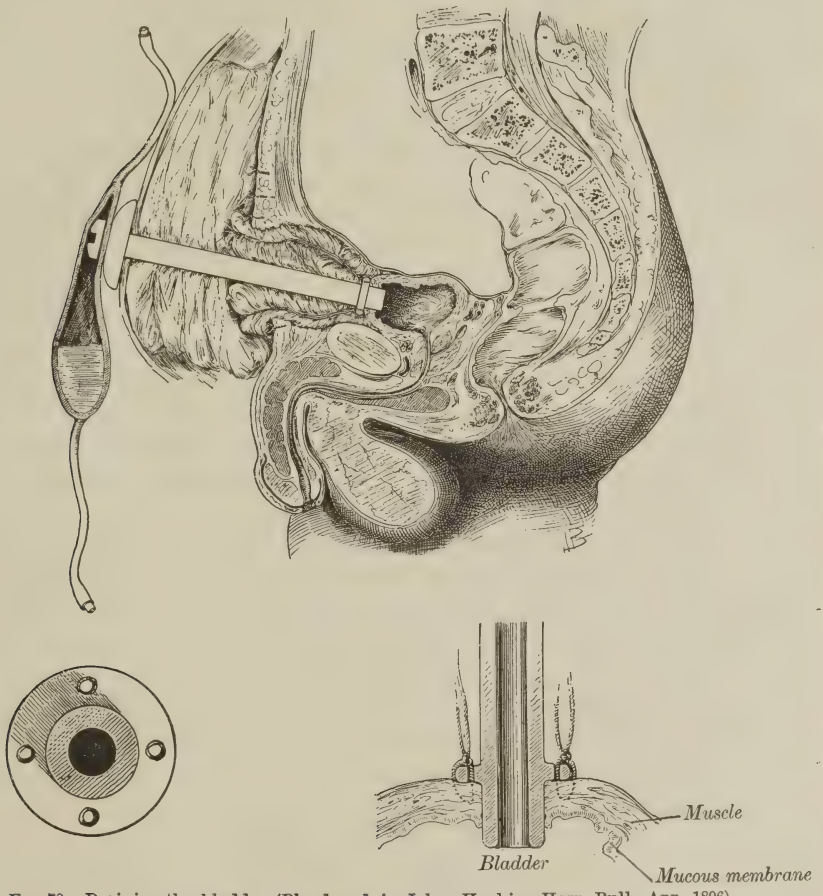

FIG. 78.—Draining the bladder (Bloodgood, in Johns Hopkins Hosp. Bull., Apr., 1896).

wall, tamponade the lower end, carry the gauze to the bottom of the pelvis, and drain the bladder by a soft catheter introduced through a perineal incision.

Heaton[1] writes upon the treatment of intraperitoneal rupture of the urinary bladder. He records a most interesting case in a woman which was cured; and says the symptoms of such an accident are—a history of direct violence to the hypogastrium when the bladder is at least moderately distended; shock and collapse, with sudden and violent burning pain in the lower abdomen; a constant desire to pass water, but with inability to pass anything but a few drops of bloody urine; if active treatment is not adopted,

[1] Ann. of Surg., June, 1896.

increasing distention and signs of fluid in the cavity of the peritoneum. Always remember that any one of these symptoms may be absent.

In cases of doubt the presence or absence of a tear may be settled by injecting into the bladder a measured amount of boracic-acid solution. If the bladder is ruptured, we will be unable to draw out all we put in.

Walsham has lately reported 2 successful cases of operation for bladder rupture.[1] He advises injection of air as suggested by Keen in doubtful cases. If there be a tear, the air will enter the peritoneal cavity, and will show its presence by abolishing the liver dulness. In Walsham's case the injection of air was followed by signs of collapse, the cause of which seems obscure.

Benjamin Bell in 1779 suggested suturing a ruptured bladder, but the operation was first performed in 1876 by Willett of St. Bartholomew's Hospital. Sir William MacCormac did the first successful operation, and the operation has been performed since 37 times. In every case abdominal section should be done, and the patient should be placed in the position of Trendelenburg, so that the intestines will not prolapse into the wound and so hide the bladder. A drainage-tube should not be used unless peritonitis exists. The rent is sewed with silk, as before described. The after-treatment is such as is usually adopted for after-abdominal operations. Most operators insert a catheter every few hours until voluntary micturition returns, but in Sir William MacCormac's second successful case no instrument was used and the patient passed water voluntarily. Out of the 37 recorded cases of abdominal section for vesical rupture, 15 cases are found to have recovered.

Legnun[2] employs **perineal drainage in cystitis** which has not been cured by ordinary methods, and in which suprapubic drainage has only been temporarily beneficial. He introduces a grooved sound into the bladder and opens the perineum by a transverse incision midway between the anus and the bulb. The urethra is opened; an instrument is passed into the bladder; the grooved sound is withdrawn. The posterior urethra is dilated by the passage of a number of instruments until it freely admits the index finger. The neck of the bladder is curetted, irrigation is employed, a Pezza catheter is inserted, and the bladder is drained for 6 weeks. Every week the instrument is taken out, cleaned, and reinserted. Every day the bladder is irrigated.

Robson[3] records a case of bladder so contracted that it could hold only ½ an ounce of fluid. By gradual fluid dilatation the capacity of the viscus was increased to 8 ounces. Every day the bladder was injected with a solution of boracic acid, moderate force being employed with the syringe. Twice the patient was anesthetized and fluid forced into the bladder.

Fenwick[4] writes upon the clinical significance of the **simple solitary ulcer of the urinary bladder.** He says that 8 years' use of the cystoscope has taught him that simple ulcers are not unusually met with, which are wrongly considered to be tubercular and incurable. Fenwick relates the case of a man of 20 who came to him 8 years ago because of constant pain in the

[1] Trans. Med.-chir. Soc., vol. lxxviii. [2] Ann. d. Mal. d. Org. Genito-urin., 1895, p. 1065.
[3] Brit. Gynæc. Jour., Aug., 1895. [4] Brit. Med. Jour., May 9, 1896.

penis and intermittent hematuria. The cystoscope showed an ulcer the size of a shilling upon the posterior wall behind the interureteral bar. The edge was raised and gelatinous; the base was bloodstained and sloughy. The patient refused operation, and yet recovered. This case drew Fenwick's attention strongly to the subject, and since then he has seen many cases of solitary ulcer. Most of them have been young men of about 20, without a venereal history. The first symptom is increased frequency of micturition, coming on suddenly; intermittent hematuria then appears. The most marked feature is constant pain in the penile urethra, which pain is much aggravated by exercise, micturition, or holding water long. The life-history of the solitary ulcer is divided into 3 stages: 1. Before the onset of cystitis; 2. The stage of cystitis; 3. The stage in which the bladder is contracted and inelastic, with mucous membrane more or less destroyed, the ureters and kidneys involved. In the first stage the urine is acid, the specific gravity still high, and pus not present in any amount. In the second stage the ulcer becomes encrusted with phosphate, and pieces of the crust break off now and then, and are passed with painful paroxysms or are retained and form calculi. In some bladders, especially female bladders, "contact" ulcers are apt to form. An ulcer forms on the anterior wall corresponding to the one on the posterior wall. The disease ought to be recognized in the first stage. We may be sure it exists without using a cystoscope, but, nevertheless, this instrument ought to be invariably employed to make certain the differential diagnosis. "In the solitary ulcer the sheen of the rest of the bladder is perfect, and the capacity is normal. In tubercle the posterior wall is patched with areas of vivid red, and peeling from them are the white flakes of necrotic tissue, whilst the capacity of the bladder is reduced at the very outset." Tuberculosis is clinically indicated if the urine is pale, murky, neutral, of a specific gravity of 1010, if there is much nocturnal irritability of the bladder, if there is a record of maternal phthisis. Solitary ulcer is clinically indicated if the urine is clear and natural colored, of a specific gravity of 1020, if there is constant penile pain and no nocturnal irritability. The prognosis of the solitary ulcer is good, and it may even heal spontaneously. Treatment in the first stage consists in the administration of oil of sandalwood, followed by the use of maltine and cod-liver oil. Fresh air and nutritious diet are insisted on, and small doses of mercury are given at night. It may become necessary to curet the ulcer. In the second stage the bladder may be irrigated with acids, nitrate of silver, or 1% lactic acid. The best thing to do in men is to perform a perineal or a suprapubic cystotomy and scrape the ulcer. In women scraping can be done without a cystotomy. It may be necessary to scrape these ulcers a number of times. A tuberculous ulcer would be made worse by the use of the curet.

Fenwick[1] says a **cystoscope** should be used in every case in which tumor of the bladder is suspected, and should be used in an interval between attacks of hematuria, so that the urine will be found clear. The surgeon should be prepared to operate at once after cystoscopy. In women pedunculated papil-

[1] Med. Press and Circ., Oct. 9, 1895.

lomata can usually be removed by way of the urethra, but the surgeon before operating should obtain permission to open the bladder if necessary (either through the vagina or above the pubes). In men the suprapubic cut is always necessary. In every growth with a pedicle the base must be thoroughly removed by cutting or by both cutting and crushing. The curet is only used upon large sessile areas or small secondary foci. Bleeding is arrested by the silk ligature (the long end left hanging out of the wound) or by the cautery applied through Keith's tube. In carcinoma we may delay the progress of the case if the disease be a hard, single, slow-growing mass, by removing with a knife the tumor base and the submucous tissue. It is useless to try and remove malignant growths which are on or about the trigone: the attempt can only do harm, and the surgeon should rest content with suprapubic drainage. Rectal and bimanual examination under ether will enable us to detect the presence of infiltrating growths. Multiple growths and "contact" growths should not be operated upon. Small malignant growths which are solitary and slow-growing can be removed even if they have reached the vesical muscle, but the whole thickness of the bladder-wall must be taken away with them. (This can be done only in the anterior, lateral, and posterior walls of the "middle zone.") If the peritoneum is removed, the bladder must be freely drained. Fenwick publishes the record of 70 cases of operation for vesical tumors (these include recurrences) with 5 deaths. Only 2 deaths were caused by the operation.

Brown[1] publishes a case in which he removed a stone by suprapubic incision, closed the bladder-wound with a continuous silk suture, and obtained primary union. Ten months later the man returned because of retention caused by the impaction of a calculus in the prostatic urethra. Perineal section was performed, the stone was removed, and it was found that **a piece of silk was the nucleus** of the mass. The silk had evidently passed entirely through the mucous membrane into the bladder.

Browne[2] says that the history of surgery is full of mistakes in **the diagnosis of vesical calculi.** Mistakes are thought to be due to the fact that a stone eludes recognition by lying in a sacculus in the posttrigonal pouch or in the postprostatic hollow. There is yet another spot where it may lie and escape detection. When we have a lateral enlargement of the prostate a pouch is formed between this enlargement and the bladder-wall, and in this pouch a stone may lie. Browne reports 3 cases. Mr. Cadge of Norwich in 1886 called attention to this fact. A stone in this situation may be missed by the sound, or may be felt by the sound and yet be unseizable by a lithotrite.

Richardson[3] records 2 cases in which he performed **intraperitoneal suprapubic lithotomy.** In very large stones the bladder may undergo such changes that an extraperitoneal operation becomes impossible, because the peritoneal reflection is found not well above, but behind or below, the pubes. This condition is due to inflammation: there is permanent thickening, and the

[1] Lancet, Feb. 22, 1896.

[2] Brit. Med. Jour., Oct. 12, 1895.

[3] Ann. of Surg., Feb., 1896.

bladder lies contracted down upon a large stone. In these cases we must take the intraperitoneal route. In Richardson's 2 cases there was no idea before operation that it would be necessary to cut the peritoneum, but the peritoneal cavity was opened at once. Both cases recovered.

Richardson concludes his paper by saying: "If further experience in intraperitoneal cystotomy shows, as I believe it will, that the dangers of peritonitis can be successfully avoided, it seems probable that the method used in the cases above reported will have an application considerably wider than it has thus far had; for in many cases of bladder tumor, of enlarged prostate, and of stone the opening in the prevesical space will be found insufficient for satisfactory manipulations. The range of the method, however, will be limited to those cases in which the perineal or urethral routes are either impracticable or injudicious, and in which the ordinary suprapubic extraperitoneal method is not feasible."

Albarran[1] of Paris reports **80 cases of lithotrity with only 1 death.** The oldest patient was 84, and he was operated on with success under cocain, general anesthesia being feared because of the existence of aortic disease.

Lithotrity in cases of stone is most ably and elaborately reviewed by Herbert Milton of Cairo.[2] In all simple cases of stone, whether in adults or in children, he considers Bigelow's operation, if in *expert* hands, the best procedure. By a simple case he means a stone of *moderate* size and density situated *in* the bladder of an adult or adolescent whose urethra is of normal size, and who has not any other important disease of the urinary organs or general system. A stone of moderate dimensions does not weigh more than 2 oz., and can be broken with a No. 12–14 instrument. A *normal* urethra readily admits an instrument of 12–14 English scale. Cases which do not conform to these conditions are complicated. He refers to complications arising from—1. Size and hardness of stone; 2. Position of stone; 3. The incomplete development of childhood; 4. Old age and its degenerations; 5. Pathologic conditions of the urinary organs; 6. The general state of the patient. The older the patient, the more dangerous the operation, provided we estimate age rather by the conditions than by the years lived. He has performed urethral lithotrity 141 times, with 3 deaths. One of the fatal cases was over 80; the second was 55, but the patient had a sacculated bladder and fetid cystitis; the third was only 35, but his kidneys were far gone with disease.

The method of Keith—that is, incising the urethra from the perineum, and passing a lithotrite from this cut through the remainder of the urethra into the bladder—should only be employed when it is impossible to introduce a lithotrite through the penile urethra. The method of Dolbeau—opening the urethra from the perineum, stretching the remainder of the tube by a dilator, and inserting a large crusher into the bladder—has not given good results. The best operation for the general surgeon to employ when attacking large stones is to open the bladder through the perineum, and through this wound crush the stone. The incision into the bladder is by the left lateral

[1] La Mercredi médicale, Nov. 6, 1896. [2] Lancet, Apr. 18–25, and May 2, 1896.

cut, and the crushing of the stone before extraction prevents much damage to important strictures.

The results obtained upon children by crushing have been remarkably good. Milton's personal experience has been small, but the truth of above statement is found in the records of Keegan and Freyer. The method should be applied to children by experts, but the general surgeon will get better results by lateral lithotomy. Gilbert Barling has published some very interesting statistics in regard to operations upon children, and these statistics indicate that the suprapubic operation is far more dangerous than many surgeons will acknowledge. Barling gives the results of 152 operations performed upon children under 10 years of age between 1888–92:

Litholapaxy,	43 cases, with	1 death.
Suprapubic lithotomy,	46	"	10 deaths.
Lateral "	48	"	2 "
Median "	15	"	1 death.
	152 cases, with	14 deaths.

The greatest difficulty the surgeon meets with is in old age, and stone-operations have a high mortality. Old men are apt to have kidney-disease, cystitis, vesical atrophy, obstruction from prostatic enlargement. These cases should not be operated upon if it seems probable that operation will produce immediate death; otherwise operation is to be advised. Crushing is the preferable operation, as it is decidedly safer. The two great dangers to be avoided are bruising by the too frequent introduction of instruments and over-distention of the bladder.

In some instances of retroprostatic pouch suprapubic lithotomy must be performed. When a stone coexists with marked prostatic enlargement, it is a matter of consideration whether it is not advisable to do a suprapubic, remove the stone, and also the prostatic enlargement. We must remember, however, that suprapubic lithotomy is more fatal than litholapaxy—that when a stone is present it is hard.

Harrison[1] says the only class of patients who may be easily **harmed by sounding** are those with enlarged prostates. Such cases should be sounded with great care, and everything should be ready for operation, so that if a stone is found the surgeon can proceed at once. Lithotrites should be strong and fenestrated, and their crushing power should be known. He believes, as does Milton, that in most cases the lithotrite should not be withdrawn until crushing is completed. When the prostate is enlarged a straight evacuating tube is used; in other cases curved tubes are best. If the urine is fetid and full of bacteria, wash out with 1 : 3000 of silver-nitrate solution. This plan was proposed by Guyon.

DISEASES OF THE PROSTATE, VAS DEFERENS, SEMINAL VESICLES, TUNICA VAGINALIS, AND TESTICLES.

Albarran[2] discusses **castration in hypertrophy of the prostate.** He concludes that when chronic retention exists, when retention is complete,

[1] Med. Chron., Oct., 1895. [2] Ann. des Mal. des Org. Gen.-urin., Dec., 1895.

or when there is a large amount of residual urine catheterization should be tried as a cure of the case, and when this fails or when the patient is very difficult to catheterize castration should be advised. [We have been confirmed in the view expressed in the *Year-Book* for 1896, that most cases can be well treated by the catheter, but that some few cases cannot; that the value of White's operation has been definitely proved; and that it has a future field of great usefulness. The abuse of the operation has led some conservative men to oppose it, but the abuse of an operation is not a scientific test of it. White himself has been very careful in all of his articles to show that only a certain number of these cases should be subjected to castration. When we properly select the cases the operation is reasonably safe, and is rapidly curative in most instances.]

Mayer[1] records some further experience as to the effect of simultaneous **ligation of both internal iliac arteries for hypertrophy of the prostate gland.** He has done it 3 times, and 2 of these cases were noted in the *Year-Book* for 1896. One patient was partially improved; 1 died from an unknown cause 7 days after operation; the 3d has not been improved at all. It should be remembered, however, that the 1st case suffered from secondary hemorrhage and the formation of a retroperitoneal abscess, yet in spite of these troubles the operation has not been in vain. It does not seem probable in the 2d case that the operation was the immediate cause of death. In the 3d case the artery was successfully tied on the one side only, and this was followed by a marked atrophy of the left lateral lobe of the prostate.

Isnardi,[2] who performed the first operation of **bilateral ligature and exsection of the vasa deferentia** in the treatment of hypertrophy of the prostate, discusses this question afresh. He has performed the operation 14 times, and he gives a record of the last 12 cases, the first 2 having been reported: 1 of the patients suffered from cancer of the prostate and committed suicide, and 1 died 9 days after the operation. Of the remaining cases, in 2 the operation was done on one side, in 9 it was done on both sides; 8 were cured of the dysuria, 2 were much improved, and 1 was not benefited. Guyon has reported 3 cases of this operation, in 2 of which the success was noticeable. Routier has reported 5 successful cases. Bussachi has operated in 3 cases with marked benefit. Chabot has reported a successful case. [We believe Mears was the first to suggest this operation.]

Burnett[3] has reported a case of a man of 35 who was operated on for stone at the age of 5. In this operation the **ejaculatory ducts** were **torn** across, becoming permanently occluded, sterility ensuing. As a result there had been an arrest of development of the prostate gland and seminal vesicles.

Spalinger[4] makes a comparison of the results obtained in the radical **treatment of hydrocele by iodin injections.** In 78 cases in Zurich, 48 were treated by iodin; of these 30 were cured, 5 relapsed, and 13 were lost

[1] Ann. of Surg., June, 1896.
[2] Therap. Woch., No. 21, 1896.
[3] Med. News, June 29, 1896.
[4] Beiträge f. klin. Chir., Bd. xiii. Heft S.; Centralbl. f. Chir., 1895, No. 27.

sight of. In 17 operations in which incision was practised, 12 were cured and 5 were lost sight of. Not one was known to have relapsed. [The open operation is the safest and best. It is the only one that permits us to promise cure.]

Lawrie[1] has devised **a new method for operating for hydrocele.** The sac is tapped in the usual way; about $\frac{1}{3}$ of the fluid is allowed to flow off, when 2 drams of a saturated solution of mercuric chlorid and glycerol are injected and mixed with the fluid which remains in the sac, and this combination is allowed to remain in the sac for $\frac{1}{2}$ to 1 minute, and the whole of it is then drawn off.

Lockwood[2] makes a strong and convincing plea for the performance of **radical cure of hydrocele by excision of the sac.** During the 10 years from 1885 to 1894, inclusive, 113 cases of hydrocele were treated by operation in the wards of St. Bartholomew's Hospital. Only 13 of these were subjected to incision; 48 were injected with iodin; 45 are said to have had a radical cure done; and 7 were treated with setons. There is no doubt that the 45 who were said to have had a radical cure done had the hydrocele injected with iodin, black wash, or phenol, or some other agent. Hydrocele is such a common disease that it is remarkable that only 110 cases have passed through the wards of this great hospital in 10 years.

Moullin[3] considers some of the recent results of **orchotomy for enlarged prostate.** He reviews his experience of 12. Of these there were 2 deaths shortly after the operation; 1 died from heart-failure on the 9th day, and the other died on the 15th day from rupture of the middle cerebral artery; 2 others died 6 months after the operation, but they would have died sooner had the operation not been performed; 2 others nearly died, not from the immediate shock of the operation, but from a form of traumatic delirium. That this traumatic delirium is not due to the loss of any specific power of the gland or of any substance which the gland forms and throws into the circulation is shown by the fact that in 2 of the recorded cases it followed unilateral orchotomy. In every case, even that of the patient who died upon the 5th day, the obstruction was diminished. In 1 of the patients who died examination after death showed that the mucous membrane that covered the vesical surface of the growth was wrinkled, and the flattened shape of the protruding prostate showed that it had been reduced in size. The microscope showed no evidence of gland-atrophy. The improvement that took place in these cases cannot be accounted for by rest in bed or other palliative measure. In all but 1 case voluntary power of micturition was regained, and residual urine fell below 2 ounces. In 1 of the patients who died postmortem examination showed the presence of a calculus which had not been suspected during life. As Moullin has met with several instances of a similar character of unsuspected calculi lying behind an enlarged prostate, he has always made a practice of specially examining for them when the symptoms are either severe or pro-

[1] Lancet, June 13, 1896. [2] Ibid., Oct. 19, 1895.

[3] Ibid., Feb. 8, 1896.

longed; 18 months ago he suggested to Prof. Clark of Glasgow that relief in enlargement of the prostate might be obtained by removing one gland. When the enlargement does not involve the median portion, but when the obstruction is caused simply by the size of the lateral lobes, he suggested that unilateral orchotomy might suffice. Since then Mr. Manning of Salisbury has done it with great success in a case; 1 or 2 successful cases have been recorded in America. If it can be shown that double ligature in section of the vas deferens acts as well, patients would probably agree to it more willingly than the other operation. We well know that section of the vas may or may not cause atrophy of the testes. The prostate appears to invariably atrophy to some degree. Both Pavone and White have proved this statement upon animals. Harrison was the first to divide the vasa deferentia in a case of enlarged prostate; 6 or 7 years later the man was alive and well. Tilden Brown ligatured both vasa deferentia under cocain in a man 72 years of age, with decided benefit. Guyon has operated twice, and Legueu once, with a certain amount of improvement, and Isnardi has also operated twice.

In another article by Moullin[1] we find a consideration of **unilateral orchotomy for enlargement of the prostate.** He says that he has recently removed the median lobe of the prostate gland in an old man who was to all intents and purposes a monorchid, for shortly after birth the left testis had been subjected at the hands of an attendant to a proceeding similar to bistourage, and as a consequence had wasted away. This case is of much interest in connection with the question of the value of the operation of unilateral orchotomy. It shows definitely that after one testicle has been lost in infancy obstruction from enlargement of the prostate may still occur later in life. We should note, however, that the cord was not divided high up and ligatured as in the operation of castration. The results, so far as the prostate is concerned, of removal of the testis alone and removal of the testes and a greater part of the cord by operation may be identical, but, though it is usually done, this should not be assumed without further evidence. Improvement has certainly taken place in some cases after unilateral orchotomy, and this may be explained by the difference in the development and growth of the prostate in different individuals. In man the prostate is in its inception a double organ: it is developed in connection with the vasa deferentia and the two sides remain more or less distinct. The seat of origin is displaced until the tubules of the gland seem connected with the urethra rather than with the ejaculatory ducts, and the two halves approach each other until, like the uterus in women, they fuse together. The degree to which the fusion varies in different people is in all probability a measure of the extent to which each testis controls the entire gland. In a patient in whom the enlargement is confined strictly to the lateral lobes unilateral orchotomy may succeed, but when there is a median outgrowth it can be of little use. The deduction is obvious that an accurate diagnosis of the special kind of enlargement is required before the unilateral operation can be condemned. Experiments to determine this point

[1] Lancet, Feb. 1, 1896.

which are made on animals in which the fusion is less complete than it is in man are of no use, for the conditions are not the same.

Kümmel[1] reports 8 of his own cases and 59 others in which **castration** was performed **for hypertrophied prostate.** He considers that the value of the operation is definitely established. He has never noticed any traumatic delirium follow the operation, and permits his patients to get up out of bed the next day.

Harrison,[2] as to **division of the vas deferens in obstructive prostatic hypertrophy,** says that a casual case of this kind came under his care some years ago and has since been reported, and in this case he practised this procedure. There is also collateral evidence in favor of the operation. Birkett and Hilton have shown that if the vasa deferentia is sectioned or ruptured atrophy of the testes results. It seems certain that in many prostatic cases it takes but a small amount of gland-shrinkage to make the difference between a life of comfort and a life of misery. Harrison is disposed to think that division of one vas or both vasa will in many cases provide the necessary relief, but even if this minor procedure should fail, the surgeon is still able to resort to castration. He discusses the effects noted as having followed the division of one vas or both vasa in the human species. In the course of a few days, as a rule, the testis shrinks or softens, and rectal examination detects analogous changes taking place in the prostate. In some cases the prostatic changes have been favored by the introduction of a catheter which followed. He has further noted that the intervals between micturition become prolonged, often double, and there is a reduced liability to bleeding and cystitis, and the urine becomes gradually normal both in appearance and composition. Prostatic spasm ceases. Some of the effects are due to diminished blood-current through the prostate.

Alexander[3] combines **perineal prostatectomy with suprapubic cystotomy.** He makes the perineal section to include the growth there, and does the suprapubic cystotomy to enable him to press down the prostate by means of the fingers, so that it can be readily included through the perineum. The mucous membrane of the bladder is not cut. At the termination of the operation the drainage-tube is carried through the cut membranous urethra into the bladder, and is allowed to remain in position for 10 days, and suprapubic drainage is also employed for the first week.

DISEASES OF THE URETER AND KIDNEY.

Kelly[4] discusses the **diagnosis of renal calculus in women.** He tells us that there is an increasing frequency of operation upon the kidney, and that serious errors of diagnosis of renal calculus are often made. The patient may have a persistent lumbar pain, blood or pus in the urine, or a retroperitoneal lumbar tumor, and yet be free from stone. The presence of pus is very significant, but when gathered from the bladder it is impossible

[1] Berl. klin., 1895, Heft 86.
[2] Feb. 22, 1896.
[3] N. Y. Med. Jour., Feb. 8, 1896.
[4] Med. News, Nov. 30, 1895.

to see from which side the pus comes. Even when the degeneration and swelling are on one side, we cannot by the ordinary methods of examination assert that the other side is completely healthy. In order to diagnose the presence of stone in the kidney, we should catheterize the ureter under direct inspection of the bladder, the bladder being distended with air by the posture of the patient. In order to gather enough urine, the catheter should be left in the ureter from a quarter of an hour to several hours. We thus determine the condition of the urine gathered from each catheter. In addition to this we should examine by means of renal bougies. For this purpose renal catheters and renal bougies should be used.

Sutton[1] says that the ureter is a muscle traversed by a channel lined with epithelium. The muscle of the **ureter** is continuous at its lower end with the muscle of the bladder, and **waves of rhythmical peristaltic contraction** pass along from the kidney to the bladder. Foster speaks of these waves as "beats," and they are subordinate to the flow of urine into the pelvis. The more active the secretion of urine the more frequent and vigorous are the beats. The ureter is not a passive conduit, but urine is conveyed along it on the same principle that fluid is conducted along the esophagus. These rhythmical contractions and their power have been studied in cases of exstrophy of the bladder. A jet of fluid has been seen to issue from the ureteral orifice 5 cm. high. The jet from the two openings may be synchronous or occasionally alternate, but, as a rule, independent in time and variable in force. Sutton records 2 cases to prove that great and unusual suffering may result from increased peristalsis of the ureter. In both of the cases it was found necessary to remove the kidney. It is an interesting fact that hydronephrosis is usually accompanied by frequency of micturition, and this is due to the fact that the beat of the ureter is exaggerated and the muscular contraction passes on to the bladder, causing vesical irritability.

Krause[2] reports a case of **fistulous communication between the ureter and the vagina.** The difficulty began after an operation for cancer. Krause opened the abdomen, divided the ureter above the fistula, and implanted it into the top of the bladder, which organ he had previously incised over a sound. He pulled the ureter into the bladder by means of a pair of forceps, and fixed it by sutures which did not penetrate the mucous coat. The patient made a good recovery.

Kelly[3] reports a case in which he performed **anastomosis of the ureter into the bladder.** After he had removed the diseased portion of the ureter he found that the part left was so short that even when he pulled upon it he could not bring it in contact with the bladder. He did not attempt to suture it to the bladder against such strong traction, as it would have separated. He freed the bladder from its attachment to the horizontal ramus of the pubis on each side. This enabled him to carry the bladder farther back in the pelvis by at least 3 cm. After having done this, he found that the ureter

[1] Lancet, May 9, 1896.

[2] Centralbl. f. Chir., 1895, No. 9.

[3] N. Am. Pract., June, 1896.

and the bladder could be easily brought together, and he proceeded to do so. The patient made an excellent recovery.

Borri[1] made a series of experiments upon dogs in the **implantation of the ureters into the intestines,** and in these experiments he used a button. The ureter is fastened about one end of the button, which is then introduced into the bowel through a small longitudinal cut, and is afterward penned up. The bobbin passes through the intestines and is discharged. He has done this successfully upon 2 cases. One was a case of tuberculosis of the bladder, and the button passed on the 8th day. Urine appeared from 16 to 24 hours after the operation, and hence afterward appeared at 2- or 3-hour intervals. In the 2d case, which was a vesico-vaginal fistula with absolute obstruction of the urethra, the button came away on the 12th day. Both cases made an excellent recovery.

Implantation of the Ureter in the Bladder.—Westermark[2] reports a case in which he operated for cancer of the cervix in the vaginal vault. He made a complete extirpation of the uterus and its appendages through a peritoneal incision. He was obliged to divide the left ureter and remove its peripheral end, together with a piece of the bladder. He closed and packed in the bladder by two layers of catgut sutures. The first layer included the superficial and muscular layers. The next layer was placed close above the other and included the superficial layer. A small opening was left in the angle of the wound, and into this the proximal end of the ureter was sutured with catgut. The needle was then passed through the outer layers of the bladder, so as to include the muscular coat, but not through the mucous membrane; then through the cut end of the ureter except mucosa, 4 mm. upward, and out through the wall; 4 sutures were passed by this method. We see that this method placed the muscular layer of the ureter in direct apposition to the same layer of the bladder, and the connective tissue of the ureter in apposition to the connective tissue of the bladder. A new layer of sutures was now made to cover the first layers. The patient made an excellent recovery.

Roberts[3] reports an interesting case in which he successfully performed **transperitoneal ureterolithotomy.** After cutting through the posterior layer of the peritoneum and lifting up the ureter, he protected the surrounding parts as much as possible and made a small opening into the ureter. He used a uterine sound, and readily passed it into the bladder, its presence there being proved by contact with a ureteral sound introduced into the bladder. He passed it upward and came in contact with a hard substance. He succeeded in causing this stone to emerge through a cut by stripping down the ureter with his fingers. The opening in the ureter was closed with silk sutures, and the peritoneum over it was closed with a continuous catgut suture. A drainage-tube was used because of the possibility of the sutures not holding. The patient made an uneventful recovery.

Tuffier[4] writes upon **partial nephrectomy** for benign tumors of the

[1] Il Policlinico, Oct. 1, 1895.
[2] Hygeia, No. 3, 1895.
[3] Ann. of Surg., Sept., 1895.
[4] Gaz. des Hôp., No. 126, 1895.

kidney. He has performed this operation in 5 cases, twice for innocent tumors, once for renal cyst, once for a kidney traumatism, and once for calculous pyonephrosis. In infiltrating tumors or tumors which are very adherent we should not attempt excision unless they are a considerable distance from the hilum of the kidney. The lumbar incision is the proper one, and hemorrhage can be arrested by temporary compression of the pedicle. The kidney must be entirely stripped from its surrounding mass of fat, and after the excision is completed it must be sutured.

Traumatism of the Kidney.—Schroeder[1] records the fact that Kölliker performed an operation upon a boy who had been injured 9 days before and who had symptoms of rupture of the kidney. A lumbar incision was made, and he found a great laceration in the kidney with sloughing edges. The upper third of the kidney was by this gap almost separated from the rest of the organ. A drainage-tube was carried into the kidney, and the entire wound was filled with iodoform-gauze. The drain was removed after 5 weeks, and the wound healed entirely in 7 weeks.

Keen[2] on the **treatment of traumatic lesions of the kidney** tabulates 155 cases compiled for him by Spencer. His tables begin where those of Maas end—that is, in 1878. He discusses gunshot wounds of the kidney, wounds of the kidney other than gunshot, and subcutaneous rupture of the kidney. The total number of cases of rupture of the kidney which appears in the table is 118. One case was under treatment when reported, and the result is not known; therefore he considers 117 cases. In these there was a mortality of 42.7%. If we are to judge rightly of the mortality, the following cases should be deducted: 1 in which the other kidney was absent; 2 in which both kidneys were injured; 2 in which the patients were found dead; and 12 which died of other additional injuries. This leaves a mortality of 33%. When no nephrectomy was done there were 13 early deaths—11 from shock and hemorrhage and 2 from peritonitis. There were 10 late deaths, of whom all died from septic causes, except 2, who died, 1 from continuous and the other from secondary hemorrhage. Had nephrectomy been done in these 23 cases, it is fair to presume that 10 of them would have recovered, which would reduce the mortality to 23%.

One of the most important things to determine is whether nephrectomy should or should not be done. The tables show a difference of 8% in favor of nephrectomy, although this operation was only performed in the most serious cases. If we count in the 13 cases which nephrectomy might have saved and the 10 late deaths, some of which early nephrectomy would have prevented, the percentage of mortality would be 33.2% against 44.2%, a difference of percentage of one-fourth. The value of nephrectomy as a life-saving operation is all the more evident when we remember that the large majority of the cases in which no operation was done were the slighter cases of injury; when nephrectomy is not done even these slight injuries show a mortality greater than the gravest injuries in which nephrectomy was done. Secondary nephrec-

[1] Münch. med. Woch., Aug. 6, 1895, p. 751.

[2] Ann. of Surg., Aug., 1896.

tomy is nearly twice as fatal as primary nephrectomy. The paper seems to indicate that lumbar nephrectomy is the safer operation. The duty of the surgeon seems clear. When the symptoms are positive, especially if there be marked evidence of hemorrhage or probable danger of sepsis, an exploratory operation should be done at once, and whether or not nephrectomy is to be done will be determined by the conditions already stated. In any case with severe and dangerous symptoms the surgeon should lean toward exploration, and in severe laceration toward early nephrectomy.

Fenger[1] as to the **conservative treatment of sacculated kidney** advised the use of a lumbar incision, and subsequent operation for the removal of valve formation in the ureter if this was found to have caused a hydronephrosis. By removing this valve we obtain a patent canal. He reported a cure of valve-formation between the sacs of a sacculated kidney. He incised the walls between the sacs, and thus produced a single sac which communicated with greater freedom with the renal pelvis. He also reported a case in which he successfully removed a portion of the kidney for tuberculosis, instead of removing the entire organ.

Franks[2] presents a most able study of the **causes and symptoms of movable kidney.** The operation which he most approves is the suture of the kidney to the 12th rib. It is known that when the kidney is hardened in situ its upper margin is marked by a groove where it is clasped by the 12th rib, and this seems to be a clear indication as to the proper position the sutured kidney should occupy. Franks sutures with catgut. He follows the plan of Lloyd, dividing the capsule of the kidney at the place where it is proposed to pass the sutures. He partially strips it off, and sutures the capsule to the renal parenchyma and the wound or to the last rib. The patient should be kept in bed for at least 6 weeks. [Access to the kidney is obtained most readily by the operation of Edebohls. The patient is placed upon his belly with the legs partly flexed. Between the belly and the bed is a rubber cylinder 9 in. in diameter, distended with air. A vertical incision is made along the edge of the erector spinæ mass, and the fatty capsule of the kidney is divided. The patient is then pulled down toward the foot of the bed, the rubber cylinder being kept from moving down. The chest now rests upon the cylinder, and is fixed by it, and the respiratory movements of the diaphragm force the kidney out through the wound, unless, of course, the kidney is enlarged.]

Casper[3] advocates the **treatment of pyelitis** with irrigations of the ureters. He makes the diagnosis by catheterizing the ureters, and then irrigates the bladder and the pelvis of the kidney with silver nitrate of the strength of 1 : 1000 at intervals of 4 days. He records several cases which promptly recovered.

Rovsing[4] says that since Kocher's first operation, 18 years ago, the **kidney** has been **removed** 150 times for malignant tumor, and the mortality has been 50 to 66% before 1890, and between 20 and 25% since that period. The

E. Q. THORNTON, M. D.,

Demonstrator of Therapeutics, Jefferson Medical College, Philadelphia.

PRICE, CLOTH, $1.25 net.

But little attention is generally given, in works on Materia Medica and Therapeutics, to the methods of combining remedies in the form of prescriptions, and this manual has been written especially for students, in the hope that it may serve to give a thorough and comprehensive knowledge of the subject.

The work, which is based upon the last (1890) edition of the *Pharmacopœia*, fully covers the subjects of Weights and Measures, Prescriptions (form of writing, general directions to pharmacist, grammatical construction, etc.), Dosage, Incompatibles, Poisons, etc.

Sent post-paid on receipt of price.

"The author has placed at the disposal of the student a work far superior to any of its class."—UNIVERSITY MEDICAL MAGAZINE.

"It will take its place in the front rank of works of its sort, and will doubtless command a large patronage."—NEW YORK MEDICAL RECORD.

"An excellent work, which covers its special line judiciously and clearly."—*Canadian Med. Review.*

JUST PUBLISHED.

PRACTICAL

POINTS IN NURSING

For Nurses in Private Practice.

WITH AN

APPENDIX

Containing Rules for Feeding the Sick; Recipes for Invalid Foods and Beverages; Weights and Measures; Dose-List; and a Full Glossary of Medical Terms and Nursing Treatment.

BY

EMILY A. M. STONEY,

Graduate of the Training School for Nurses, Lawrence, Mass.; Superintendent of the Training School for Nurses, Carney Hospital, South Boston, Mass.

"This is a well-written, eminently practical volume."—*American Journal of Obstetrics.*

A HANDSOME VOLUME OF 456 PAGES, CONTAINING 73 ILLUSTRATIONS IN THE TEXT, AND 9 COLORED AND HALF-TONE PLATES.

PRICE, $1.75 net.

The author treats, in popular language and in the shortest possible form, the entire range of *private* nursing as distinguished from hospital nursing, and instructs the nurse how best to meet the various emergencies of medical and surgical cases when distant from aid or when thrown on her own resources.

An especially valuable feature of the work will be found in the directions for quickly improvising needed sick-room appliances.

Sent post-paid on receipt of price.

W. B. SAUNDERS, Publisher,

large mortality is due to the fact that diagnosis has been made late instead of early.

Legueu[1] has collected 20 cases which he calls **renal neuralgia** in which operation was done; nothing was found, and yet the condition was permanently cured. One point in the diagnosis of these latter cases should be that the urine is sterile and contains no pus. He says that, whereas in the vast majority of cases we should be able to reach a correct diagnosis, when there is doubt as to whether we are dealing with tumor or a calculus we should make a lumbar exploration. If stone in the kidney is accompanied by suppuration, operation is absolutely indicated, since life is threatened. If suppuration does not exist, operation may be deferred. Severe hemorrhage or frequent hemorrhages or agonizing pains make operation perfectly necessary, but there are some chronic cases in which this operation is not imperatively demanded. The author then discusses the palliative treatment and the operations. He tells us that incision of the pelvis of the kidney causes but little bleeding, and does not injure the parenchymatous structure of the kidney, but, unfortunately, this incision does not permit us to remove calculi which are in the parenchyma and the calyces of the kidney, and that a permanent urinary fistula is very likely to follow. Nephrolithotomy enables the surgeon to remove all concretions, whether they lie in the pelvis or in the parenchyma. When suppuration is absent this wound in the kidney should be used, but when suppuration is present the wound should be drained and partially sewn. Hemorrhage can be prevented by temporary digital compression or by compression of the instrument. Extirpation is only exceptionally needed. We employ it when the kidney-substance is extensively destroyed, and when the fact that the later urine contains a large amount of urea shows us that the other kidney is fit to undertake the task alone. The mortality of nephrectomy for stone is 40%, and this is usually due to the fact that the other kidney is diseased and breaks down under the strain. The prognosis is good—7 deaths out of 115 cases.

Albarran[2] in discussing the treatment of **movable kidney** thinks that orthopedic apparatus are of the very greatest value. Belts are of great use. They may require to be fitted again. They often make the patient entirely comfortable. He believes in operating if the apparatus fails to give relief or if the movable kidney is also diseased. Often when the kidney causes pain a well-padded belt will make the patient comfortable. In neurasthenia or hysteria when a belt or drainage fails we are justified in operating. Even if an operation is done, a belt should be worn.

Meyer[3] in an article upon **"The Early Diagnosis of Tuberculosis of the Kidney"** says that when tuberculosis is advanced to a certain stage cystoscopy of the bladder would be absolutely the diagnosis of primary descending tuberculosis. We find a healthy surface of the vesical mucous membrane and one normal ureteral opening. The other ureteral mouth is injected, and between it and the slightly hyperemic trigone we see a number of circum-

[1] Arch. f. klin. Chir., Bd. li. Heft 4. [2] Ann. des Mal. des Org. Genito-urin., July, 1895.
[3] Med. News, Mar. 7, 1896.

scribed inflammatory areas of the mucous membrane, the interposed tissue being unchanged in appearance. Meyer compares this appearance to foot-prints in freshly fallen snow. No other disease of the bladder presents a similar cystoscopic appearance.

WOUNDS, BURNS, ULCERS, AND PLASTIC SURGERY.

Neebe[1] uses zinc-jelly bandage very largely in **the treatment of leg-ulcers.** In addition to this he applies iodoform or weak silver-nitrate ointment to the ulcer. If the floor of the ulcer is necrotic, Neebe holds that mercury and carbolic mucilage should be applied to it until the slough separates. For the treatment of excessive granulation he applies a preparation containing 1 part of silver nitrate, 10 parts of balsam of Peru, 100 parts of vaseline. This ointment greatly aids cicatrization. The zinc-jelly bandage is changed about once a week. [In instituting treatment for an ulcer a surgeon should invariably determine the variety and condition of the ulcer. Remedies which are valuable in one condition may be harmful in another. It is not enough to say that certain remedies are to be used in the treatment of ulcer; we must say what is the kind of ulcer, and what the stage of ulceration, and what the complications. In describing an ulcer give the supposed cause, the situation, the duration, the degree of acuteness, the number of ulcers, the state of the floor, the base, and edges, the discharge, and the condition of surrounding parts.]

Auger[2] applies olive oil in the treatment of **bruises.** He applies the oil with great freedom and rubs it in with fingers, and covers the bruised area with materials saturated with it. He maintains that this treatment immediately relieves the pain and enables superficial wounds to heal rapidly. [Centuries ago inunctions of oil were used for treating bruises. The oil permits of easy and gentle massage, and the massage rather than the oil is the therapeutic agent.]

Broadnax[3] advises treating **burns** by the application of **pure phenol.** Pain instantly ceases, and the only dressing necessary is lint or cotton and a bandage. [This treatment seems heroic and unnecessarily severe. We may get excellent results by milder methods. Phenol might cause gangrene. For 4 years past in the out-patient surgical department of Jefferson Hospital many burns have been treated with normal salt-solution. The plan has given great satisfaction. The solution allays the pain quickly and certainly, and greatly aids rapid granulation. The part is wrapped in cotton soaked in normal salt-solution, a bandage is applied, a trapdoor is cut in the bandage to permit of frequent additions of the solution, and the burnt region is as far as possible put at rest. If skin-grafting becomes necessary, we find the raw surface well prepared for the reception of grafts. We commend this plan to the attention of the profession.]

Leistikow[4] is a strong advocate of the use of **ichthyol in burns.** In

[1] Therap. Gaz., Nov. 15, 1895.
[2] Semaine méd., 1895, xv. p. cxcviii.
[3] Quoted in Physician and Surgeon, Apr., 1896.
[4] Semaine méd., 1895, xv. p. 487.

burns of the first degree he uses a mixture of 5 parts of zinc oxide, 10 parts of carbonated magnesium, and from 1 to 2 parts of ichthyol. In burns of the second degree he applies the following composition: 5 parts of zinc oxid; 10 of prepared chalk; 10 of starch; 10 of linseed oil; 10 of lime-water; and from 1 to 3 of ichthyôl. This material is applied once daily. When there is a great deal of inflammation in the burn these two preparations can be used at the same time, the burn being first dusted with the powder, and the paste being laid on over this.

Poggi[1] treats a burn by the **application of potash** in the form of baths or lotions or compresses steeped in a saturated solution of this material. Potassium nitrate in water is a refrigerant and rapidly abolishes the pain of the burn. Such a bath applied for 2 or 3 hours frequently permanently dispels the pain. The application of compresses saturated in this solution acts in the same manner. [A trial of this method shows that it possesses considerable power in relieving pain, but not more than the method by salt-solution. A 2% solution of cocain quickly dispels the intense early pain of a burn, and Schleich's fluid does so too. An excellent drug with which to treat burns is a solution of citrate of lime, originally suggested to us by Johnston. It relieves pain and favors granulation. We have used it in a number of cases. The antiseptic treatment of burns gives excellent results, but its application causes considerable pain—so much, in fact, that it may be necessary to give an anesthetic to put on the first dressing. (See *Year-Book* for 1896.)]

The following **ointment for burns** is recommended by Dr. Haas:[2] from 75 to 150 gr. of aristol, 300 of olive oil, and 600 each of lanolin and vaselin. [If an ointment is used, the old-fashioned zinc ointment is very soothing. The trouble with its use is that suppuration arises, crusts form, and the detachment of the crusts during dressing causes much pain. The best way to remove such crusts is to soften them by the use of a spray of hydrogen peroxid projected from an atomizer. Ordinary white-lead paint was a favorite application of the elder Gross. Cosmolin should not be applied to burns of the face, because it may give rise to pigmentation.]

Picric acid for burns was originally recommended by Thierry.[3] It is said to cause immediate cessation of the pain. The remedy is not toxic, and the yellow stains produced by it may be easily removed with boric acid.

Fenwick and Barnard[4] consider **burns in children.** The plan of treatment pursued in the London Hospital is as follows: When the child is brought in severely burned it is wrapped in a blanket without having its clothes removed. Hot-water bottles are applied, and tincture of opium and brandy are given and repeated if necessary. When the patient reacts, one part after another is exposed and dressed with zinc ointment and cotton wool, and as soon as it is once more dressed it is covered with a blanket. In about 4 days suppuration again commences, and the dressings are at that time changed. Opium and brandy are given as necessary during the treatment of the case to

[3] Chem. and Drug., Nov., 1895.
[4] Brit. Med. Jour., Dec. 7, 1895.

allay pain. Diarrhea must be treated the minute it arises. The prescription they prefer consists of 10 gr. of bismuth carbonate, 3 minims of the wine of ipecac, 3 of the tincture of opium, 15 of the tincture of mucilage, and 2 drams of distilled water, repeated every 4 hours.

Coombs[1] discusses the proper method to treat **powder-burns.** He says that in a few days suppuration occurs, and at this time a poultice is applied for a half hour or longer, and then a sharp razor is passed over the surface, which cuts off the soft elevations which contain the powder. The burn is then washed off with a stiff sponge, and the remaining grains of powder are caught in the meshes. The latter is cleaned and the wiping and mopping repeated until the coloring matter is absorbed by the sponge. In order to prevent subsequent cicatrization-marks as much as possible, a constant dressing of glycerol and water or glycerol of starch is recommended.

Reclus[2] presents the conservative treatment in **crushes of the limbs.** He thinks that this is preferable to amputation, no matter how extensive the traumatism may be. He wraps the crushed limb in antiseptic substances, and leaves the dead tissue to be separated from the living by natural processes, and he only makes incision in the bone when the time comes and at the proper point. This method greatly reduces the mortality from these injuries, which is excessively high when amputation is done for traumatism. He states that 2 cases out of 4 would unquestionably have perished had he amputated at the hip-joint or amputated both legs at the time he first saw them; and the results of the treatment are that the patient whose hip would have been disarticulated retained the thigh, and the patient whose lower extremities would have been amputated at the thigh retained one-half of both legs, so that he can readily apply prosthetic apparatus.

In another case in which if he had followed old rules both legs would have been sacrificed the patient recovered, and did not even lose his feet. The method is as follows: The hair is shaved from the limb; the skin is carefully cleansed with soap and water, ether, potassium permanganate, and alcohol. The edges of the wounds are thoroughly explored, so as to open up all passages and pockets, and these pockets, as well as the entire wound, are irrigated with water at a temperature of 65° C. This irrigation removes clots and foreign bodies of all sorts which are adherent to the structures. The tissues should be strongly rubbed with cotton balls which are soaked in some antiseptic. When the whole region has been thoroughly asepticized strips of gauze are covered with an ointment which he advises, and these strips are introduced into every cavity, sinus, passageway, diverticulum, and separate part. The soft tissues are brought together around the wound, and a moist gauze bandage is applied somewhat tightly. He renews this dressing every second or third week. The ointment which he advises for embalming the injured part consists of 3 drams of salol, 3 of resorcin, 3 of antipyrin, 5 of boric acid, 15 gr. of iodoform, 6 oz. of vaseline. These ingredients are but slightly capable of absorption. The results of this treatment are extremely remarkable. Out of

[1] Chemist's Gaz., Jan., 1896.

[2] Med. Week., iii. No. 45, p. 530.

7 cases which in former times would have undergone extensive operation, 6 recovered perfectly with the whole of the crushed limb or a considerable part of it preserved. The 7th died of tetanus 25 days after the accident, so that now Reclus advises we should give with the treatment antitetanic serum.

Miles[1] furnishes notes on **skin-grafts obtained from the lower animals.** He has used dogs, rabbits, kittens, and frogs as the donors. The best results are obtained from dogs, and the least satisfactory from frogs. Young animals should always be used. The ulcer should be first made aseptic, and the granulations must be healthy, neither redundant nor edematous. The granulations are not scraped before applying the grafts. In preparing the grafts the animal is killed, the abdomen is shaved, and the entire skin is dissected up, leaving behind the subcutaneous tissue. The skin is floated out in warm boric acid, and cut in pieces varying in size according to the raw surface to be covered in (from 1 in. by $\frac{1}{2}$ in. to 6 in. by 1 in.). These pieces are firmly pressed into the granulating surfaces close into the margins, edge being against edge. Dressing of protective gauze and wool, with a splint, is then applied. This primary dressing is left undisturbed for 2 or 3 days, and then is changed with the greatest caution, and subsequently we dress every day or every second day. If the graft dies, it should be at once removed to prevent septic changes. Occasionally sloughing is observed in a graft. Pustules which appear upon a recently grafted surface ought to be punctured and covered with an antiseptic dressing; if granulations grow up through the grafts, these granulations must be spooned away. In all these cases rest is of the utmost importance. The scars obtained by this method are stronger and show less tendency to contract than those obtained by any other method. The pigment over the grafted skin rapidly disappears, and no hair, sweat, or sebaceous matter appears.

Mangoldt[2] advises **skin-grafting** by small portions **of epithelium,** which he obtains by scraping the cutaneous surface with a sharp razor held vertical. The scraping is carried on until the top of the papillæ are reached. If we are going to graft a granulating surface, this should be lightly scraped; but if we are going to graft a simple wound, the surface ought to be carefully dried. The scrapings are dusted over the surface.

Amat[3] has employed the **membrane of a hen's egg in grafting.** He advises that the membrane be taken from a fresh egg. Grafting must not be done during the existence of suppuration. The egg is broken in its center; its contents are emptied out, and the lining membrane of the shell is seized with rat-tooth forceps at the large end of the egg. This layer is cut into strips about 4 or 5 mm. in width and of the same length, and these are applied on the wound with their albuminous surface down. They are covered with tinfoil and then with gauze saturated in phenol.

Lusk[4] reports cases illustrative of the advantages of a new and original method of obtaining material for **skin-grafting.** This method consists in

the **formation of blisters** by cantharides and by grafting portions of the elevated epidermis.

THE RÖNTGEN RAYS.

[One of the most marvellous of all recent discoveries—a discovery which is of equal importance to physical science and to surgical diagnosis, which radically overturns many preconceived and long-cherished opinions, and which opens up an infinite vista to those who dream of the future, is that of Prof. Röntgen of Würzburg. This discovery enables us to obtain pictures through hitherto opaque media. A great number of valuable articles have been contributed on this subject during the year, and every day brings forth some new fact which clears up a mooted question. The whole question is in a transition-stage, and it is possible in such a work as this to quote but a few of the important articles of the year.]

Monell[1] discusses Röntgen's contribution to surgical diagnosis. Röntgen's report, which is destined to be historical, was presented to the Physico-medical Society of Würzburg in December of 1895. Monell says that the entire report is a masterpiece of technical statement—that it is deliberate, exact, and scientific, and leaves no room whatever to doubt either the proof or the means of the discovery. A synopsis of the report is then given.

Monell considers the methods employed by Edison, Tesla, and Professor Pupin. The first instrument designed as a fluoroscope was a brass tube blackened on the inside, to one end of which was secured by nonactinic black photographic paper a circular disk of paper prepared with the double cyanide of platinum and barium. The opposite end of the tube was fitted to the eye, so that light was excluded, and directed toward the excited vacuum tube, so that the rays fell upon the fluorescent screen, which then glowed and revealed the shadows of objects between it and the Crookes tube. Magie calls a similar device of his a skiascope, and Salvioni called his a cryptoscope. Dr. Emmen invented the photoscope; Edison devised the fluoroscope in which the screen is tungstate-of-calcium crystals. Prof. Röntgen employed a fluoroscope in his own experiments. In fact, it was a fluorescing screen which led him to detect the rays. Objects which are transparent to the Röntgen rays do not present any color-phenomena corresponding to the color given by common light. This is a decided drawback. When this process is developed to the highest point, it is probable that only trained experts will be able to do the work which surgeons will require for diagnostic purposes. Monell then fully describes the methods of obtaining these pictures. Spies of Berlin was the first after Röntgen to make a picture of a man's hand in which something had caused pain for many years. The negative showed a piece of glass, which was immediately extracted. In Berlin new bone-fractures were immediately photographed, and united fractures were shown through their dressings and splints. In London a wounded sailor who had received a mysterious injury was subjected to the process, and a small knife blade was found imbedded in the spine, having pro-

[1] Brooklyn Med. Jour., May, 1896.

duced paralysis. Neusser of Vienna obtained pictures of gall-stones from one patient and a bladder-calculus from another patient. The printed proofs of pictures or the half-tone reproductions are but poor representations of the real aid to diagnosis of this new process. All prints from negatives are unsatisfactory. It is the negative alone which presents the delicate shade and the even outlines which are necessary for distinctness. Nothing but the properly developed negative is suitable for a surgeon's examination. Consideration is then given to some of Tesla's remarkable work. He asks, in conclusion: "What are the actual facts to be observed in Röntgen's pictures?" We can detect presence, shape, outline, and size of bodies through the living tissues. We can locate bony or metallic material, but can only outline soft parts and masses of muscle. We cannot determine consistence, color, substance, structure, or condition; we can outline the thoracic cavity or the gastric wall, but we cannot tell whether the lungs or the mucous membrane of the stomach are normal or inflamed. A pus-cavity may prove to be more opaque to the rays than healthy tissues; so may a cirrhotic liver, a malignant tumor, or a gravid womb. The difference between fibrous and bony ankylosis, fracture and dislocation, will be certainly shown, but there is no reason to doubt that wonderful progress will take place in the future, and it seems probable that at some day we shall observe with the eye even the circulation of the blood.

The first successful modification of the action of the rays, so that varying density of tissues will lend themselves to the process of the new art, will bring all morbid growths of vital organs, of injuries, of deformities, even the vermiform appendix, within the visual and photographic field, but for the present we must pause. Improved methods must come before further advance, and for them we must look to the physicist and the photographic expert.

Fowler[1] in a preliminary note upon the possibilities of the application of photography of unseen substances to surgical diagnosis says that it would seem that the surgery of the bony structures of the body, as well as that of foreign bodies imbedded in the soft parts, has received a fresh impetus in the shape of improved methods of diagnosis. He thinks that it will be of great value in obscure cases of fracture, in cases in which, owing to excessive swelling of the parts, an accurate estimate of the exact relations of bony fragments to each other is impossible by the ordinary diagnostic methods. It enables us to be sure that efficient reduction has taken place, and obtains a trustworthy record of the conditions present which may be used for subsequent study and as a means of defence in cases of alleged malpractice. It will enable us to study the changes which the tarsal bones undergo in the course of treatment of cases of congenital varus by manipulation and orthopedic appliances. Foreign bodies imbedded in the soft tissues can be located with certainty, save in the case of gunshot injury to the contents of the cranial cavity and when bullets are imbedded in the substance of the bones.

Keen,[2] Magie, and Davis made some experiments to determine the value of the Röntgen process in surgical diagnosis. They examined a number of

[1] Brooklyn Med. Jour., Mar., 1896.

[2] Am. Jour. Med. Sci., Mar., 1896.

surgical cases: 1. A burned hand with ankylosis of the fingers at the knuckle-joints and some necrosis of the metacarpal bones. The skiagraph showed the bones in the fingers. The bones of the metacarpus were shown to be completely soldered together in one mass. 2. A tubercular elbow-joint in which not only the humerus, but the radius and ulna, were shown. 3. The elbow-joint of a man who had sustained, 12 years before, an intercondyloid fracture. The picture showed excellently the condition. 4. An elbow which had been resected a few days before. The arm was dressed in plaster of Paris with a trapdoor over the joint. The skiagraph showed that the plaster was opaque to the rays, but the gauze dressing and bandage about the elbow were translucent to them. The ends of the resected bones of the forearm showed faintly, and the end of the humerus also. 5. Shoulder-joint with a recent resection of 3 inches of the humerus. The picture was taken without removing the bandage and dressing, but the skiagraph showed only the outline of the edge of the scapula. The constant respiratory movement was a difficulty which tended to blur the outline. 6. Attempts to skiagraph the trephine-opening of a case operated upon 4 years ago were a failure. 7. A needle thrust into the hand of a cadaver. Experiments do not indicate that the hand of a living person acts differently to the rays than the hand of a dead person. 8. Exposure of various bacteria to the rays seemed to be without effect.

These records, taken with various other reports which have been made, show that the thinner portions of the body may be accurately skiagraphed. This is true of parts as thick as the ordinary elbow. Whether it is true of the thicker parts, as the shoulder and trunk, is doubtful with present methods. One of the difficulties has been the length of time necessary to take the pictures, the shortest exposure having been 20 minutes. The normal structures of the body are all permeable to the rays except the bones, and therefore it is not probable with present methods that we can determine much about these normal structures, although the British Medical Journal for the 8th of February, 1896, states that Adolph and Lenz have been able to get pictures of connective tissue. The bones are opaque to the rays; hence the deformities, injuries, and diseases of bone will be more or less amenable to diagnosis. An excellent illustration of this is a case recently quoted in the British Medical Journal, in which the distal phalanx of the great toe appeared to be double, as though there were two bones in the last joint. It was difficult to tell which of the two bones was the normal and which the supernumerary. Mosetig took a skiagraph, and was able instantly to determine. We shall probably be able, even possibly in the thicker parts of the body, to differentiate fracture and dislocation. This may be of much use in obscure cases with great swelling, for the swelling is permeable to the rays. Suspected green-stick fracture may be made evident, and in any case in which possibly a claim for malpractice would be made if, after the bones are adjusted, they are skiagraphed through the dressings, such a skiagraph might be of great value in court. Exostoses and bony tumors of any kind may be diagnosticated, but cartilage is translucent to the rays. Gall-stones have been skiagraphed outside of the

body, but not yet in the living body. Phosphatic and probably other urinary calculi are impermeable to the Röntgen rays, but it is very doubtful whether we shall be able to diagnose these conditions by the rays, because the bladder lies in the pelvic basin and the bones would cut off the rays. The kidneys cannot be skiagraphed, as that part of the body is too thick, and renal calculi are as yet beyond diagnosis by this method. It is doubtful whether the diagnosis of tumors will be much aided, except in the case of bony tumors. Other tumors seem to be as translucent as the soft parts of the body. This method is absolutely useless in diagnosticating tumors of the brain. The most important use of the method is in the location of foreign bodies. Some metals are translucent to the rays; others, and, fortunately, the common ones, are not translucent. We can find a needle which is suspected to be lodged in any part of the hand; buckshot, bullets, and glass.

The case of a young colored woman is then related who had 3 months before suffered amputation of the 3d finger. The stump was extremely sensitive. A skiagraph showed a slight enlargement of the tissues next the bone. In view of the fact that no one point at the end of the stump was demonstrated to be in a condition capable of cure by operation, the patient was advised to have the metacarpal bone removed.

Carless[1] reviews the **surgical aspects of the new photography,** and says that we are at the beginning of a new chapter. He describes in brief the method of taking these pictures. He tells us that the electrical current employed was from a battery of six Grove cells, giving a current of about 10 volts, which was passed through a Rühmkorff's coil, and this multiplied so as to reach a sufficiently high voltage to give a 3- or 4-inch spark.

Mr. Carless then considers the already very extensive literature on the subject, and says that there is great difficulty in gauging the value of the work, owing to the imperfect records that are given as to the length of exposure and as to whether the pictures came from the living subject or the cadaver. Many highly eulogistic reports should be received with considerable skepticism. The question as to the relative transparency of the tissues has attracted much consideration. Bergonié[2] and Reid[3] have considered this question. The former ascertained that the relative transparency of all the soft parts is practically identical, and that cartilage is the most transparent of all the tissues. The latter observer confirms this statement, and says that fat comes next to cartilage in transparency, that the cortex of the kidneys is more permeable than the pyramids, that in the brain the white matter allowed the rays to pass more readily than the gray, and that cancerous tissue is just as transparent as the normal tissue in which it lies. Bergonié shows that foreign bodies, especially those made of metal, with the exception of aluminum, can be readily detected under certain favorable conditions. The actual thickness of the interposed tissue must not be too great. It is probably impossible to detect a ball in the liver or lung, because the tissue thickness is too great and portions of bony

[1] Practitioner, Mar., 1896. [2] Jour. de Méd. de Bordeaux, Feb. 9, 1896.
[3] Brit. Med. Jour., Feb. 15, 1896.

skeleton are in the way. The optical laws governing the formation of the umbra and penumbra are such that if the foreign body is placed at too great a distance from the source of actinic energy, and it is impossible to concentrate this energy, then a vague and confused shadow is the best that can be expected. He showed that the sharp outlines of a needle are lost if it is imbedded in the hand at a greater depth than 1½ cm.

Neusser[1] has found that vesical calculi are opaque, and expresses the hope that we may obtain diagnostic aid in liver and bladder troubles. In injected parts of the dead body the blood-vessels are reproduced with clearness.

Lannelongue[2] has 3 interesting skiagraphs. The first is an anatomical preparation, a femur attacked by acute osteomyelitis. Certain white spots appear in the midst of the shadow, and thus the fact once more is demonstrated that this disease starts centrally in the medulla and not in the periosteum. The second picture was a finger with tubercular dactylitis; the first phalanx was enlarged and the periosteum evidently infiltrated. The second phalanx was more transparent than normal, indicating commencing osteitis.

Mosetig[3] has skiagraphed 2 cases. One was a hand in which a bullet was imbedded, the site of which could not be detected by touch. The second was a photograph of an enlarged great toe of a girl, in which it was proved that the trouble was due to the presence of an accessory terminal phalanx.

Jastrowritz[4] relates a case in which the rays enabled him to locate a splinter of glass in the hand. Petersen[5] gives 5 illustrations. One was the forearm of a corpse which was preserved in formalin, and in which fracture of the radius and ulna had been produced. The fracture is seen with tolerable clearness. There has also been an attempt to portray the tibia and fibula, but with very little success. Bar[6] has published a series of 9 illustrations, chiefly taken from infants or portions of the infant cadaver. Other cases have been mentioned in papers both lay and scientific, but he has found no accurate records of them. It is stated that Prof. Kocher has found and removed a needle in a child's hand—that a similar case occurred at St. Thomas's Hospital, and again at Leeds.

In conclusion, Mr. Carless asks what is the value of the Röntgen process from a surgical standpoint. We must remember that it is in its earliest infancy, and that we can speak of it only in the most guarded fashion. If the intensity of the rays can be increased, or if means are found to affect their reflection or refraction, then we may have to reconsider our verdict, but as things are at present there is little doubt that the part played by it will not be one of great importance. Obscure injuries and conditions of the fingers and toes will be early recognized, and it will be useful in solving diagnostic questions in these regions, although even here the majority of them will be recognized just as easily by the educated touch of the skilled surgeon. Injuries and diseases of the wrist will be little helped by the process, except in young

PLATE 1.

1

2

FIG. 1.—Showing result in a case of metatarsalgia after excision of the fourth metatarsophalangeal joint. FIG. 2.—Distortion of foot, showing deviation of phalanges; crowding of the third and fifth metatarsal bones upon the head of the fourth. (Morton, in Int. Med. Mag., June, 1896.)

children, where the bones are still partly cartilaginous, while the majority of such conditions as could be portrayed in the upper and more bulky parts of the adult arm and leg can usually be readily recognized without any such help. There is some ground for hoping that assistance may be derived from the transparency of tubercular tissue in the diagnosis and localization of isolated foci in the bones of children. Cancerous and other tumors are transparent to the rays unless bony tissue is present, and it is possible that a malignant tumor of bone might receive confirmatory evidence of its existence by this process. Transparency of cartilage leads us to expect that assistance will be obtained in diagnosticating separated epiphyses and fractures implicating the joints of children. Conditions within the abdomen and chest cannot be investigated by this method because of the thickness of the parts.

Burry[1] discusses the **Röntgen or *x*-rays,** gives a history of their discovery, explains what is known about them, and gives the history of an interesting case.

King[2] had 1 case in which **a speck of steel broken off from a needle** was detected in the finger. He has succeeded in making a skiagraph of a 3-months' fetus, which rather clearly defines the center of ossification, and shows how clearly at this age the bone restrains the rays, while the cartilage allows them to pass freely; also one of a wrist on which an excision has been performed, which gives a clear outline.

Morton[3] shows the value of the *x*-rays in diagnosticating Morton's **painful affection of the foot, or metatarsalgia.** The real pathology of this disease was uncertain. Morton maintained that the 4th toe was the almost invariable seat of origin of the trouble, because of anatomic reasons. There is very slight motion in the first 3 metatarsal bones; the 4th has greater mobility, and the 5th more than the 4th. Lateral pressure brings the head of the 5th metatarsal into direct contact with the head and neck of the 4th metatarsal, and to some extent the extremity of the 5th metatarsal rolls above or under the 4th metatarsal, and thus by pressing upon nerves induces neuralgia. This supposed pathology is amply proved by the skiagraphs which are herewith given (see Plate 1).

Marsh[4] reports a case in which a man when riding a horse had the horse fall and roll over him. The left arm was enormously swollen, and it was not possible to give a precise opinion. The Röntgen photograph clearly showed dislocation backward at the elbow-joint, which injury was uncomplicated by a fracture.

Smith[5] speaks of the detection of **spinal caries** by the Röntgen process. He reports a case in which he was uncertain as to the exact diagnosis. A skiagraph proved the absence of tubercular disease, as the shadows produced by the cervical and upper dorsal vertebræ were quite regular, and there were no signs of roughness of bone nor indication of an abscess. In the 2d case

[1] Chicago Med. Recorder, Mar., 1896.

[3] Internat. Med. Mag., June, 1896.
[4] Brit. Med. Jour., May 30, 1896.
[5] Ibid., June 6, 1896.

he thought that caries of the cervical vertebræ existed, and he had it skiagraphed. The skiagraph showed from the 2d to the 7th cervical vertebra. The intervertebral spaces between the 4th and 5th, the 5th and 6th, and the 6th and 7th were distinguished by light shading, but above the 4th there seemed to be a mass of bone and no sign of cartilage. The appearance of the bone showed the severity of the disease and the amount of repair, and the value of the examination could not be overestimated. It cleared up all doubts as to the nature of the case and indicated the line for future treatment. It is in the neck that this diagnostic process must be most applicable, for, except in very young children, the obstruction caused by the sternum and other dense tissues interferes with a satisfactory shadow.

Morton[1] demonstrated a needle in the foot. Battle[2] showed a needle extracted from the hand by the assistance of the Röntgen rays. M'Causland[3] showed a case of a needle which was found by the use of the Röntgen rays in the palm of the hand. Jones[4] reports a case in which a bullet lost in the wrist was discovered by means of the Röntgen rays.

White[5] reported a case of **a jack-stone** caught in the esophagus of an infant, discovered by the *x*-rays. White tells us that in Poulet's work upon foreign bodies over 1000 cases of foreign bodies in the esophagus are studied, but the list of nearly 100 different obstructing articles does not include a jack-stone. In this case the skiagraph was taken 13 days after the accident. The child's arms were held up, the plate was fastened to the back, and an exposure of 3 minutes was employed by Goodspeed. The jack-stone was distinctly visible in the negative, and was seen to be a little to the left of the middle line, on a level with the space between the 2d and 3d dorsal spines, a little above the bifurcation of the trachea. Attempts to reach the foreign body with forceps failed. Gastrotomy was performed. A flexible esophageal bougie carrying a stout silk thread was then passed into the stomach from the mouth. Pieces of gauze of various sizes were knotted to the thread at various points, and the thread was moved up and down. The stone was dislodged and was brought into the stomach and removed. The wounds in the stomach and abdominal wall were closed, and the patient recovered rapidly. [This is a brilliant case. Strange to say, a few weeks after this operation, Dr. Alfred C. Wood, one of Dr. White's assistants, had an identical case, which, by the same plan, was conducted to a successful conclusion.]

Turner[6] has discussed this new process, and has reported cases in which foreign bodies were found—cases of bone surgery and applications of the method to teaching. One case was a woman who had a needle in her hand which was detected by these rays (Figs. 79, 80). Another case was a woman who had run a needle into her foot. The fluoroscope showed that the needle, between $\frac{1}{4}$ and $\frac{1}{2}$ in. long, was present, and exploratory incision failed to find it. The wound was sewed up and rephotographed. The picture again showed

the needle. Experiments were conducted with a skeleton foot on the screen, and the same shadows were found to be produced by a needle lying in the sheath of the peroneus longus; so the wound was opened and the sheath and tendon carefully explored, but no trace of the needle was found. The foot was then skiagraphed in 4 different positions with a guide-needle placed in the

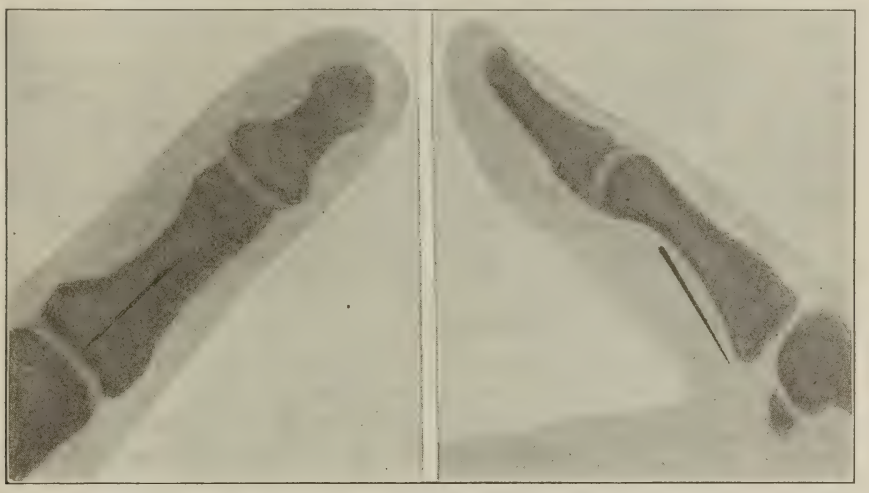

FIG. 79.—Needle shown through the phalanx; the palmar surface of the thumb was on the plate (Turner, in Lancet, June 20, 1896).

FIG. 80.—Side view of thumb; the hand was pronated, so that the radial surface was on the plate (Turner, in Lancet, June 20, 1896).

wound, and the relationship of the 2 thus determined, and a third operation was undertaken, but was equally unsuccessful. A skiagraph taken after the wound healed distinctly revealed the needle in the same position. This case shows very clearly the great difficulty which may be experienced in removing a foreign body when one has only the shadow to work from.

Turner says that the application to general bone-surgery is not chiefly from a diagnostic point of view. He has not skiagraphed a single case where the diagnosis was materially altered, but he has several times confirmed a diagnosis and found out the exact extent of an injury. It is very valuable in fractures to ascertain the extent of injuries, especially the amount of comminution and longitudinal splitting of the bone. He took a skiagraph in the ward without disturbing the patient, the splints and dressings being untouched; extension from the leg was not even removed. He relates the case of a man who had a compound comminuted fracture of the tibia and fibula and a simple fracture of the femur of the same side. The lower fractures were explored, some loose portions of bone removed, and a wire placed through the tibia. A skiagraph taken 5 weeks after the accident showed longitudinal splitting of both bones with a large amount of comminution, and also shows that the early callus is very transparent to these rays and does not show. A skiagraph of the femur with an $8\frac{1}{2}$-minute exposure shows impaction at the shaft of the bone at the junction of its upper and middle thirds, the upper part being split into two pieces, enclosing the conical-shaped upper end of the lower fragment. Cases can be

skiagraphed through water-glasses, allowing the surgeon to watch the progress of the case. Figure 81 shows the case of a man who broke his right radius. Eleven months later, the fracture being ununited, a piece was taken out of the ulna and both bones were wired. The illustration showed that osseous union

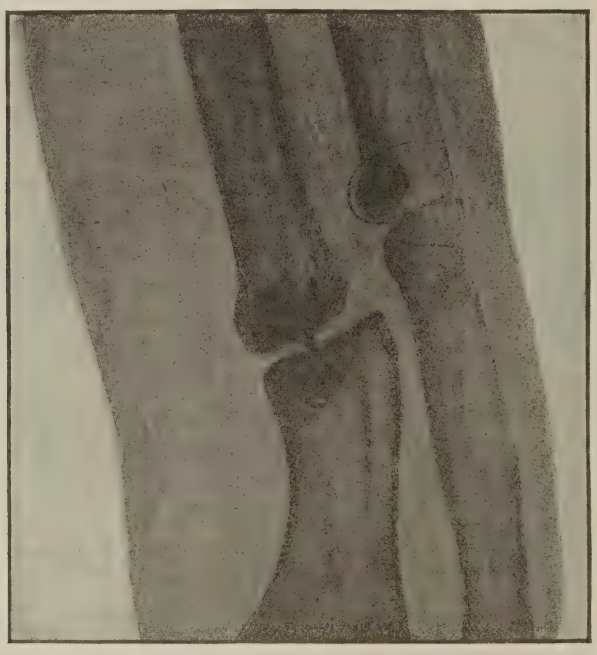

Fig. 81.—Reproduction of photograph of fractured radius and ulna, showing no union and wires which had been put in; exposure six and a half minutes (Turner, in Lancet, June 27, 1896).

had not as yet taken place. This process is valuable in injuries about the elbow-joint. In deformities it may also be found useful—for instance, in exactly locating the position of the curve of the femur and the absence or presence of a metatarsal or metacarpal bone.

Turner thinks that the Röntgen process can be used with the utmost benefit in teaching students osteology, showing the method of the growth of bones, with the epiphyses, their positions, their appearance at different ages, their date of union, and the diaphysis. It can be used in teaching surgery. The skiagraph of the knee-joint which he has taken would enable the teacher to point out to the student the importance of remembering the position of the epiphysis, and the line of cartilage from which the bones grow when excision is about to be performed, and to emphasize the importance of not injuring the cartilage. The skiagraph of the two wrists of a patient (Fig. 82) shows clearly to the student their position and differences taken in the dorsopalmar position with an exposure of 4 minutes, and the fellows of them taken in the radioulnar position with 6 minutes' exposure, demonstrating to the student (*a*) the position of a Colles fracture, (*b*) the clinical evidences of it, and (*c*) the causation of the deformity. The position of the corresponding styloid pro-

cess is rendered clear, the prominence on the dorsal surface being produced by the backward and upward displacement of the lower fragment, that on the palmar surface being due to the projection of the lower end of the upper fragment. The rotation of the lower fragment on its anteroposterior axis, the consequent abduction of the hand and prominence of the styloid process of

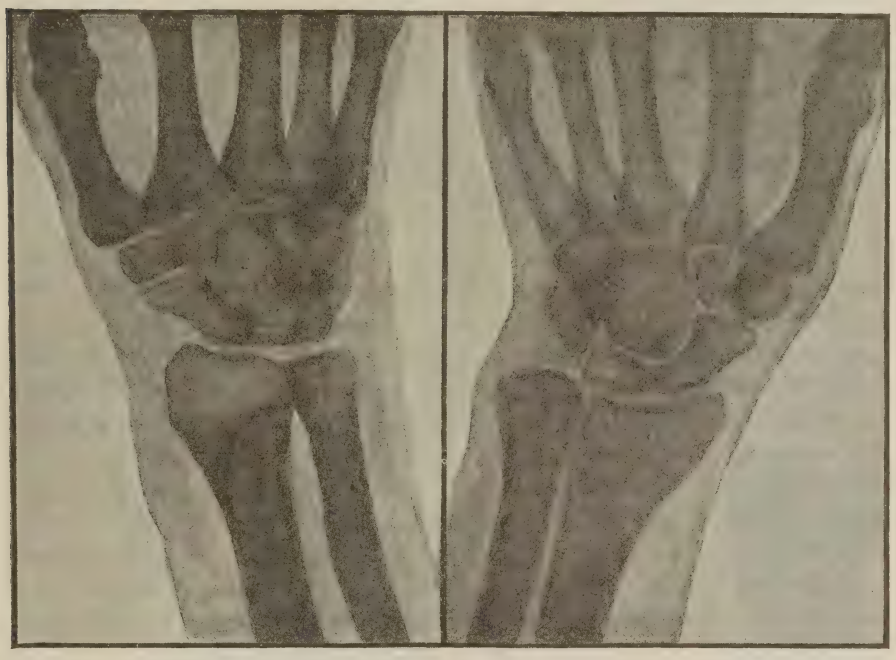

FIG. 82.—1, skiagraph of a Colles' fracture: the line of fracture appears across the lower end of the radius; 2, a normal wrist-joint, for comparison with preceding illustration (Turner, in Lancet, June 27, 1896).

the ulna, and the rotation of the lower fragment on its transverse axis, with resulting extension of the hand at the wrist-joint, are also shown.

MILITARY SURGERY.

Conservative Surgery on the Battle-field and First Aid to the Wounded.—Under this title Senn[1] says: Conservatism will be a characteristic of the coming days of military surgery. The two great dangers, hemorrhage and infection, will be enormously diminished. Mutilating primary operations will be limited to injuries which extensively destroy the soft parts, and complications of large vessels and nerves which are in themselves severe enough to arrest nutrition in a limb. Gunshot injuries of bones and joints will no longer render primary resection or amputation imperatively necessary, and the danger of wounds which penetrate cavities will be greatly lessened. Prompt and efficient aid to the injured is the first essential of battle-field surgery, and it can be achieved only by means of a well-trained hospital corps, and it must be entrusted largely to the educated noncombatant soldier.

[1] Jour. Am. Med. Assoc., July 6, 1895.

Temporary Hemostasis.—A large percentage of battle-field deaths have always been due to hemorrhage. The use of the modern small bullet, which travels with great velocity and has a high penetrating power, will render deaths from acute primary hemorrhage more frequent. The modern bullet inflicts a sort of incised wound; the round or large conical bullet causes a contused wound. Wounds from the older-style projectiles were frequently followed by sloughing and secondary hemorrhage. In primary hemorrhage ligation upon the field will rarely be performed, the operation being done at the first dressing-station or field-hospital. It is rarely essential to distinguish between venous and arterial bleeding, in order to effect a temporary arrest. The means used to temporarily arrest bleeding are—1. *Elevation of Limb.*—It can be effected as is shown in Figures 83 and 84. 2. *Digital Compression.*

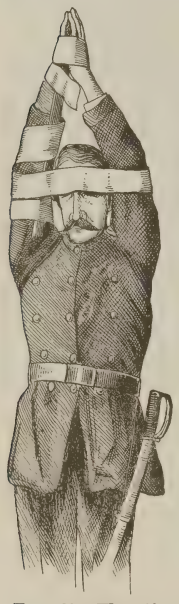

FIG. 83.—Elevation of the upper extremity in the treatment of hemorrhage (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

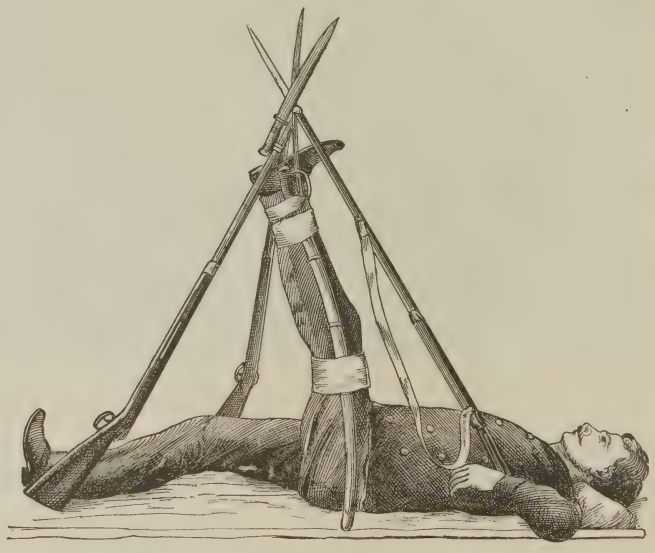

FIG. 84.—Gun-stack for elevation of the lower extremity (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

—This is continued until the ligation of the vessel or until the application of an elastic band or an antiseptic tampon. 3. *Forced Flexion.*—Forced flexion of the forearm can be made by a handkerchief. Forced flexion of knee is obtained by passing a bandage, suspender, gun-strap, or belt through a slit in the shoe above the heel, tying the ends over the thigh, and fastening it with a safety-pin (Figs. 85 and 86). 4. *Elastic constriction* is safe and certain. The limb is elevated for a few moments, and Von Esmarch's band or a suspender is applied above the wound. In order to prevent injurious compression upon nerves, try and apply the band at a point where the main nerves are

well protected by muscles (for the arm constrict around the middle of the deltoid or over the top of the shoulder; for the thigh, near its base). It is entirely safe to maintain elastic constriction for from 4 to 6 hours, but it would be unwise to continue it longer. 5. *Antiseptic Tampon.*—Every soldier

FIG. 85.—Genuflexion in the treatment of hemorrhage from the popliteal artery and its branches (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

carries an antiseptic package. The wound is dusted with antiseptic powder, a graduated compress is made, and its apex is brought in contact with the bleeding vessel, and pressure is made by a bandage. This method is of great value

FIG. 86.—Forced flexion of forearm in arresting hemorrhage from the brachial artery opposite the elbow-joint or any of its branches below this point (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

FIG. 87.—Antiseptic tamponade of wound of deep palmar arch (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

in injuries of face, scalp, and intercostal spaces, in lacerated wounds and sabre wounds, and often arrests bleeding permanently (Figs. 87, 88).

Internal Hemorrhage.—The opening of the cavity which contains the

bleeding vessel will be done at the first dressing-station. What can be done upon the field of battle: In bleeding from intracranial vessels due to bullet-wound, do *not* plug, as the accumulating blood would cause death by cerebral compression. Insert into the track of the projectile a strip of aseptic or of iodoform-gauze. This gauze-drain prevents disastrous pressure, and tends to check bleeding by being in contact with the vessel. Secure the drain to the wound-surface by a safety-pin, and dress the wound antiseptically. In bullet wounds and stab wounds of the chest use the antiseptic tampon and apply circular compression of the chest by means of a bandage. The cartridge-belt or gun-strap may be used to limit respiratory movements (Fig. 88).

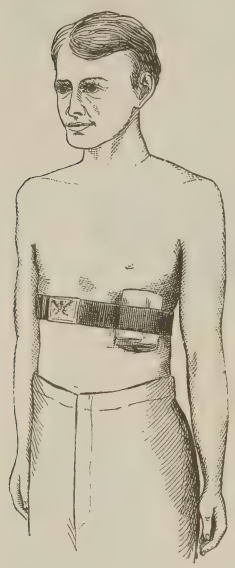

FIG. 88. — Treatment of penetrating wound of chest by antiseptic tamponage and immobilization by circular compression (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

In abdominal wounds in which the source of bleeding is below the bifurcation of the aorta apply compression to the aorta (Fig. 89). In other cases put gauze over wound, lay a large compress over the gauze, and apply circular compression by a belt or gun-strap. The direct compression diminishes the vascularity of the underlying parts, and the circular compression limits abdominal movement.

Permanent Hemostasis.—1. *Forcipressure.*—The use of the forceps on the battle-field will be a great advance. 2. *Ligature.*—Ligation will usually be done at the first dressing-station or field-hospital. Silk should be used in military service. 3. *Vein-suture and lateral ligature* are used in small wounds of large veins and sinuses. Suture is applied like the Lembert, and either silk or catgut can be used. 4. *Hot Water and Styptics.*—Styptics are used only in

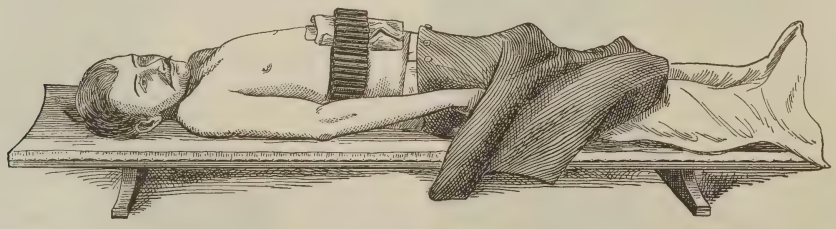

FIG. 89.—Compression of abdominal aorta (after Esmarch) (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

bleeding from mouth and pharynx where tamponade cannot be used. Hot water (120°–130°) is very valuable in parenchymatous hemorrhage. *Saline infusion* is very valuable when people are dangerously debilitated by bleeding. It restores a normal degree of intracardiac and intravascular pressure. Szumann's solution is used (NaCl 6, Na_2CO_3 1, H_2O 1000). A fountain syringe is used, and the median basilic vein receives the injection. The vein is exposed, a ligature is thrown loosely around it, a glass tube is inserted toward

the body, the ligature is tightened to hold the tube in place. From 500 to 1500 grams are injected.

Autotransfusion is of service. By excluding unessential parts from the general circulation we secure for the vital parts a sufficient supply of blood. One or more of the extremities is elevated to render it bloodless, and constriction is applied high up.

Shock is often difficult to differentiate from hemorrhage. The maximum of shock is almost immediately after the accident. In hemorrhage the symptoms progressively increase. Shock must be actively treated—recumbency, active stimulation and external heat, alcohol, camphor, ammonia, amyl nitrite, strychnin. No important operation is undertaken until reaction is brought about.

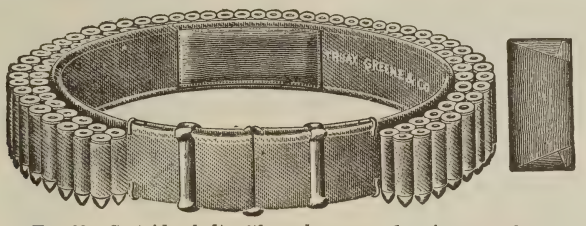

FIG. 90.—Cartridge-belt with package sewed on inner surface.

Primary dressing is applied as soon as possible. The materials are obtained from the package carried by the soldier. Esmarch thinks the package should be kept sewed into the uniform. Senn thinks it should be sewed upon the inner surface of the cartridge-belt (Fig. 90). The package should contain ½ oz. of compressed salicylated cotton and a triangular gauze bandage. In the center of the cotton is a powder (½ g. of salicylic acid and 2 g. of boracic acid). The cotton is surrounded by the gauze bandage, which has stuck in it a safety-pin, and the whole is wrapped in gutta-percha tissue. In applying the dressing the cotton is loosened, the

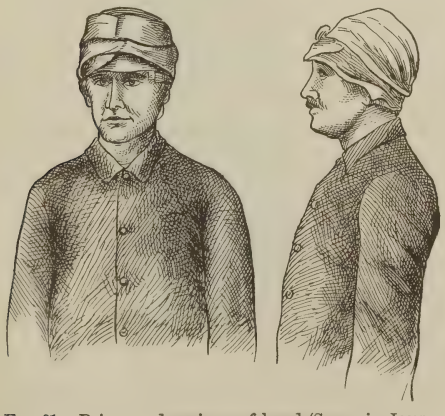

FIG. 91.—Primary dressings of head (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

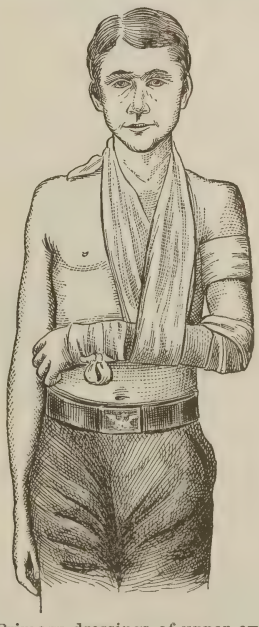

FIG. 92.—Primary dressings of upper extremities (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

wound is dusted with the powder and well covered with the cotton, and the dressing held in place by the triangular bandage and various extemporized

FIG. 93.—Primary dressings of lower extremities (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

appliances (see Figs. 91–93). The drying powder is a very important addition, because the dressings soon saturate with blood and the powder prevents the blood from decomposing.

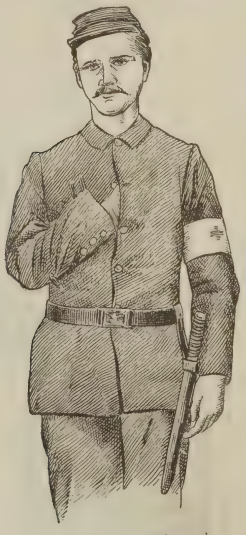

FIG. 94.—Immobilization of arm and forearm by fastening the sleeve to the coat near the wrist- and elbow-joints with safety-pins and inserting hand underneath coat on opposite side between two buttons (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

FIG. 95.—Mitella by fastening lapel of coat on injured side with two safety-pins in such a position as to support the forearm in a flexed position (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

Immobilization of Joints and Limbs.—This is brought about by various expedients (see Figs. 94–98).

In the Field Hospital.—It is here that hemorrhage is permanently arrested, that patients are restored from shock, that grave wounds are examined

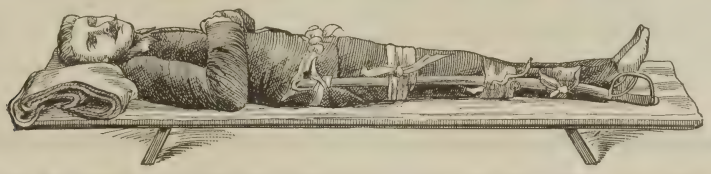

FIG. 96.—Saber splint for leg and thigh (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

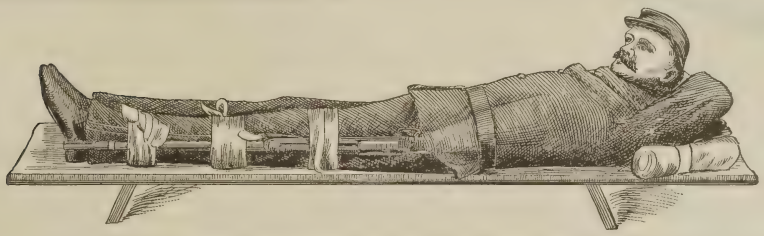

FIG. 97.—Gun splint (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

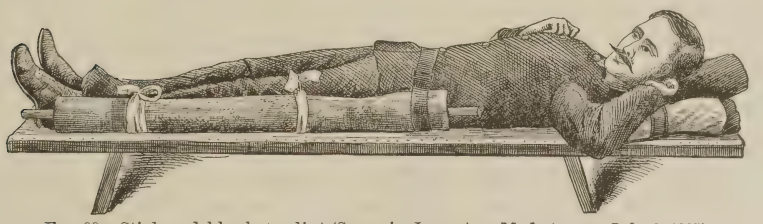

FIG. 98.—Stick and blanket splint (Senn, in Jour. Am. Med. Assoc., July 6, 1895).

and treated with antiseptic care, that the skull and abdomen are opened for penetrating wounds, and that plaster of Paris is applied instead of temporary fixation in cases of compound fracture and penetrating joint wounds.

Indications for Probing and Extracting the Ball.—The bullet-probe is rarely needed in injuries inflicted by the modern small-caliber bullet, because the great velocity and power of penetration of this projectile causes it in many cases to pass through the body regardless of resistance of bone. When a wound of exit exists, do not probe. The modern bullet is rarely altered in shape, and rarely deflected by striking bone. Search for the bullet, if undertaken, requires absolute aseptic care, and is justifiable in gunshot fractures and penetrating wounds of cranium and joints. It is absolutely contraindicated in penetrating wounds of chest and abdomen. In bullet wounds of the soft parts probing is justifiable if there is reason to think that the ball is located in an accessible place. If a bullet can only be removed by a formidable operation, let it alone and await indications. The modern bullet, like the old leaden ball, is apt to become encysted, and when encysted is harmless. The hard metal jacket of the modern projectile renders less useful the Nélaton probe and the American bullet-forceps. Nevertheless, the Nélaton probe is a good instrument to follow the track of the ball. The bulb should be longer than that usually made. It should be nearly the size of the bullet (Fig. 99). In using the probe try

to place the parts and tissues, if possible, in the position they occupied when struck. Employ no more force in using a bullet-probe than in introducing a catheter. If a bullet can be felt under the skin opposite the wound of entrance, extract it without exploring the track of the ball. If the bullet is lodged in a region in which its presence will prevent good function (as in a joint), enlarge

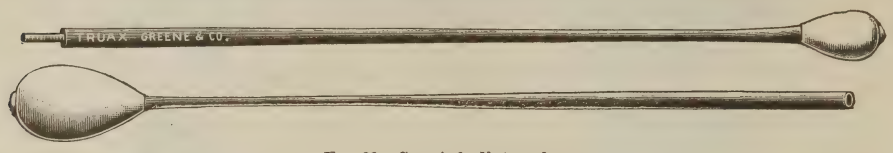

FIG. 99.—Senn's bullet probe.

the wound of entrance and remove the ball. Bullet-forceps must have great power of grasping. In gunshot wounds of the skull use Flührer's aluminum probe by his method of operating.

In every penetrating wound of the cranium, operate. We operate in order to stop bleeding, render the wound aseptic, remove bone spicules, foreign bodies, and, if possible, the bullet.

Celiotomy is advisable in penetrating wounds of abdomen. Primary amputation for gunshot wound is only justified by extensive injury of soft parts and fractures and joint-wounds complicated by injury of large vessels and nerves. In every doubtful case try to save the limb.

Primary resection of joints for gunshot wounds is obsolete in military surgery. Such joint-injuries are disinfected, the fragments of bone and foreign bodies are removed, a gauze drain is inserted, and the limb is immobilized in plaster of Paris. Many cases will be saved; none will eventually require secondary resection or amputation.

MacCormac,[1] **discussing some points of interest in connection with the surgery of war,** says: The modern rifle has produced great changes. It sends a small and hard projectile with enormous velocity to a great distance, and this projectile is a great advance not only upon the round bullet of Brown Bess, but upon the ovoid bullet of the needle gun and the cylindroconoidal bullet of the Minié rifle and the Chassepôt. The Lee-Metford rifle with white powder was used very successfully by the British in the Wazingstan expedition and in Chitral; the volleys were almost smokeless and noiseless, and were very destructive. Examples of gunshot injury from this source have not come to hand.

Fractures were shown produced by the Chassepôt and needle-gun. Some show great shattering, some guttering, some a keyhole opening with a long fissure running from it. The only chance to study the effects of the modern bullet upon the human living body is in accidents and suicides. Most of our studies are of the effects upon animals and cadavers. The study of the effect upon a dead body is not exactly representative of the effect upon a living body. Many experiments have been made at short range with small charges of pow-

[1] Brit. Med. Jour., Aug. 3, 1895.

der, the short range enabling us to certainly strike the target; but results got by this method are very different from those with full charges. During the last 20 years the caliber of the rifle and the size of the projectile have progressively diminished, while the hardness of the bullet has greatly increased.

The following table sets forth the most important particulars as to rifles and projectiles used in different countries:

Small-caliber Magazine Rifles and Bullets.

Country.	Pattern of rifle.	Year.	Caliber.		Bullet.	Length in inches of bullet.	Diameter of bullet in inches.	Weight in grains.	Muzzle velocity in foot-seconds.	Sighted to yards.	Range in yards.
			Millimeters.	Inches.

	Martini-Henri.	1872	. . . .	0.45	Hardened lead.	1.27	0,45	480 to 410			

We find from this table that the modern rifle has a nearly identical caliber in each of the European armies (from 7–8 mm.), and that the weight of the projectile is nearly identical, except in Spain and Roumania (215–225 gr.). The form is an elongated cylinder with a rounded extremity, composed of a core of hardened lead and a jacket of steel, copper, nickel, or German silver. Its length is four times its width, and the rifling gives to it a rotary movement of 2500 revolutions per second and a muzzle velocity of 1800–2500 ft. per second. The English army employs a projectile which has a core of lead hardened with antimony and a jacket of nickel hardened with copper. It weighs 215 gr., and upon impact is not apt to change its shape, as was the old leaden bullet. Its small size, its hardness, its great velocity, and its penetrating power cause it to inflict remarkable wounds. The range is about 3500 yd. (over 2 miles); the trajectory is flatter, and the direction truer, because of diminished aerial resistance and greater driving power.

The amount of damage inflicted by a gunshot wound is determined by the unalterable form of the projectile, its size, its velocity on impact, and the tissue-resistance. Hitherto nine-tenths of the wounded were disabled by rifle bullets, and the perforation will not be less from the modern magazine guns, which fire 60 shots a minute and carry an immense distance.

Bruns, Delorme, Habart, and Lagarde made experiments with short ranges and reduced charges, so as to reduce velocity to about the degree that the projectiles at 100, 500, or 1000 yd. would have with full charges. Wounds inflicted in this manner are not so grave as those produced by the old leaden rifle bullet. These experiments showed that at what corresponded to short ranges (up to 400 yd.) explosive effects were produced by both the old bullet and the new, and the injuries did not materially differ. At 250–300 yd. the old bullet ceased to cause these effects; the new bullet produced them up to 350–400 yd., or even much farther. The extent of explosive effect depends upon high velocity, size and hardness of projectile, and resistance of the part impacted. Vascular tissues, organs like the liver and spleen, full stomach, brain, and full intestines suffer most from this explosive effect. We do not refer to an injury caused by an explosive bullet. The entrance wound is not peculiar, but the internal soft parts are pulpefied, and this pulpefaction extends for a considerable distance around the bullet track. The wound of exit is large and lacerated. Bone, if struck, is comminuted, powdered, and driven widely into the surrounding tissues. The wound about the bone is conical, the base at the surface, the apex at the bone.

If a bullet be fired through an empty tin box or an empty skull, both the wounds of exit and entrance correspond nearly to the size of the bullet. If a bullet be fired through a tin box filled with damp clay, water, jelly, or wet sawdust, the box bursts asunder.

Wm. Busch was the first to suggest that these effects arose from a sudden increase of hydraulic pressure. This pressure is not truly hydraulic, as it is not exerted equally in all directions, but largely in the direction in which the projectile moves. It occurs *almost* equally in closed and open vessels filled with fluid or jelly. The increase in cubical volume of the contents upon being struck is in a closed vessel nearly $\frac{1}{3}$, and in an open vessel $\frac{1}{4}$ or $\frac{1}{5}$ (as much as 300 times the bulk of the projectile). Water has an enormous resistance to a bullet. The bullet has probably traversed the part before hydraulic influence takes effect. This effect is obviously due to the retarding effect of fluid upon the flight of the projectile, the motion of the projectile being transferred to the parts immediately around, and from them to parts farther removed, as circles of waves are produced by dropping a stone into smooth water. A study of reduced charges would indicate that empty viscera and elastic lung do not suffer from explosive effects (Bruns' studies); the skull and semifluid organs show them to a fearful extent. Between 400 and 800 yd. explosive effects are only manifest upon the skull, not in other regions; between 800 and 1200 yd. explosive effects are rare, even in skull, and less destructive. At this range Bruns holds that the track in the soft parts is narrower than the bullet; the wound of exit a little larger; in expanded ends of bones no fissures or but slight fissures are formed. Beyond 1200 yd. the projectile begins to wobble, and damage becomes more extensive.

The Prussian authorities, struck with contradictory results set forth by experimenters with reduced charges, had made experiments with full charges,

and the results obtained were compared with those noted in individuals who were shot while living (suicides or accident cases), and were found to correspond.

The bodies were clothed in shirts and injected with Wickersheimer's solution (to give them proper fluidity). Two methods were employed to estimate damage: 1. Freezing and making a section of the track of the ball; 2. Making a cast in fusible metal of the interior of the wound, and thus getting a model of the destroyed area.

Nine hundred experiments do not confirm the accuracy of Bruns' claim that gunshot wounds can be classified according to range; as the range increases the extent of injury diminishes.

"It must be remembered, however, that the projectile produces different effects on different organs and different parts of the body, according to their density or fluidity, and even the same part or organ in different individuals will present differences which materially affect the extent of the damage done by bullets fired from equal distances, so that the range of fire cannot be determined with precision from the extent of the injury inflicted. Nor does the size of the entrance wound enable one to draw any definite conclusion. It is larger at short ranges than at longer ones, varying from 7.6 mm. (0.3 in.) at 100 yd. to 5.0 mm. (0.2 in.) at 2000 yd. range. When the bullet strikes perpendicularly to the surface the opening will be circular with smooth edges, which after an interval become dry and brown. If the skin be wrinkled or loose, the wound will be stellate, and when the bullet strikes obliquely or transversely, it may be large and ragged. The exit wound is larger and more variable in shape than the wound of entrance. When the projectile emerges perpendicularly to the tissues traversed, the exit wound is circular in about 20% of the injuries, while a circular shape in the wound of entrance is twice as frequent.

"The bullet in nearly every case was found to go straight through the part struck, and the old-fashioned contour shot was never met with. The human body is traversed with ease at 2000 yd., and the skull, thorax, and abdomen will suffer alike. At less than half this distance the old bullet has lost most of its momentum, and becomes flattened out or impacted when it strikes a bone without penetrating deeply.

"Portions of clothing were found in the wound in only 2 cases up to 600 m. range, but they appear to have been carried in in about 12% of the total number.

"*Wounds of Abdomen.*—In these injuries the liver showed the largest amount of damage, and in some cases of suicide large portions of it were reduced to pulp. Up to 1200 yd. the entrance wound was usually large and stellate and the exit track funnel-shaped, with lateral rents extending from it.

"In the spleen and kidneys similar injuries were produced. In the intestine each bullet produced on an average three openings, and in some cases as many as eight, and the extent of the damage seemed to bear no defined relation to the length of range. It was more extensive when the intestine was full. At the entrance wound and, to a lesser extent, at the wound of exit, the bullet caused more damage to the serous coat of the intestine than to the mucous, while in the stomach the converse obtained, and the mucous coat was more extensively injured than the serous.

"*Injury of the Head.*—Fearful destruction of skull is produced by a small 5 mm. (0.2 in.) bullet at 50 yd. range. The vault is completely shattered, the base extensively split open, and the brain destroyed. The 8 mm. bullet produces similar results, but, as a rule, the fragments hold together. At 100 yd. the entire vault is shattered, fissures extend from both entrance and exit wounds, and a gaping line of fracture was constantly found extending between them. The fissuring around the wounds of exit and entrance shows two different types—one circular, the other radiating—and the base is also traversed

by fissures. Up to 1600 yd. the fissures gradually diminish or disappear, with the exception of the one connecting the entrance and exit wounds, and sometimes a clean perforation occurs, which becomes frequent at 2000 yd. The skull when emptied of the brain shows a round keyhole perforation at all distances, but if it be filled with jelly, the amount and character of injury are the same as when it is occupied by brain-substance. The dura is lacerated to an extent corresponding to the injury to the bone. At short range the brain is pulpefied and numerous blood extravasations are found in its substance and beneath the meninges. At long range the bullet track through the brain tissue is cylindrical, the walls are moderately contused, and the caliber of the channel is always less than that of the bullet. Portions of the skull may be carried in at the entrance wound for some distance by the bullet, so that there the injury, as a rule, will be most severe.

"*Injury to the Long Bones.*—Gunshot fractures are very frequent and possess great interest. They vary according to which bone or part of the bone is struck. The effect upon the spongy extremities and upon the compact tissue is very different. From 100 to 200 yd. the shaft of the femur is broken up into small pieces for an extent of from 3 to 5 in., and the humerus from 2 to 6 in. At the entrance wound in the bone the fragments remain in part attached to the soft parts, but at the wound of exit they are completely separated. The adjacent muscles are filled with bone débris and detached fragments of bone, the muscles and tendons are torn, and the exit wound in the soft parts is large and ragged. In the spongy bones and spongy extremities of the long bones the crushing and fissuring at short range are also great, but the fissures are often concealed by untorn periosteum, and there is less damage to the soft parts at the wound of exit.

"At a range of 600 yd. there are occasionally keyhole shots, with radiating fissures in the spongy tissue, and at 800 yd. the keyhole channels become frequent, but even up to 1600 yd. or more the compact tissue is extensively fractured. At 1200 yd. the fragments of bone, as a rule, are no longer driven into the soft parts beyond, but this happens occasionally even up to 2000 yd.

"The conclusion to be drawn from the German experiments is that the damage to the shaft of a long bone is very extensive for all ranges up to 2000 yd., the main difference being that at short ranges of 200 or 300 yd., for example, the fragments are more numerous, smaller, and more stripped of periosteum, while the converse obtains at longer ranges.

"The damage done to the soft parts lying between the fractured bone and the wound of exit is enormous at short distances. Above 700 yd. the exit wound becomes smaller and the internal damage begins to diminish.

"The experiments also show that the minute external openings these bullets make often bear an inverse proportion to the amount of internal damage. Very small openings of entrance and exit are compatible with enormous destruction of the compact bone tissue traversed by the ball between. The current opinion that the new bullet causes on the whole less serious damage than the old seems scarcely well founded. It was devised certainly with no humane intention, but in order to incapacitate by killing and wounding as many men as possible in the shortest possible time, and it seems admirably devised to ensure this result.

"*Deformation of the Projectile.*—The liability to change in form is a very important element in the amount of damage caused by a bullet. A leaden ball is flattened or spread out on striking a bone; it may be grooved by a tendon or fascia or split into several pieces. The amount of deformity depends on the momentum of the bullet, the result of its weight and velocity combined, as well as the resistance of the part of the body struck. The new bullet may traverse the body with little or no alteration in shape, or the resistance may be great enough to crush or split it with a corresponding increment of developed heat. The tip only may be flattened or the whole bullet converted into mushroom form, with separation of the jacket. The harder the bullet, the less, other things being alike, is the tendency to deformation and the greater the penetrating power. The total number of altered bullets amounted to 4.5%, but if only cases in which the bone is

implicated be taken, the proportion is considerably increased. In the hard bones of the horse it amounts to as much as 14%.

"Wounds involving the soft parts only never produce any alteration of shape, while the compact tissue of the long bones causes the maximum amount of deformity. The jacketed projectile passes through spongy bones and soft parts without change. Even at short ranges and after striking compact bone its tip may be only slightly flattened or bent. A portion of the jacket is sometimes stripped off, and this accident is most frequent with the nickel envelope used for the American rifle bullet, the French Lebel rifle, and in our own arm.

"It may be affirmed that the extent of the damage inflicted increases proportionately with the amount of deformation in the bullet. The separation of the jacket and dislodgement of the leaden core occasion injury which often exceeds in degree that of the old leaden bullet, and this was observed at even so long a range as 1000 yd. A bullet deformed by ricochet will also cause extensive damage, but somewhat differently, as the entrance track will be implicated, as well as the channel beyond the bone."

The penetrating power of a bullet is in proportion to the square of its striking velocity, but is also much influenced by its density, by its form, and by the unchangeability of its shape. The modern projectile is less likely than the old to lodge in the body, because of its small size, its hardness, and the velocity with which it is propelled. It nearly always passes through instead of lodging in the parts struck, and we therefore avoid much after-trouble.

Habart and Chauvel have found that up to 1500 or even 2000 yd. the hard bullet goes completely through the body, and Bruns says that the projectile never lodges up to 200 yd. Thus we see that the disastrous attempts to extract lodged bullets will in future be largely done away with. Of course there will in time of war be many irregular kinds of injury—those, for instance, which richochet shots produce, the bullet having struck the wall or the ground, and altering its shape and direction, and then being capable of inflicting terrible injury. A long range increases the liability to this occurrence. It is much less common now than in the old bullet to have pieces of clothing carried into the wound, although this still maintains in about 12% of cases. The primary hemorrhage was rarely produced by the old leaden bullet unless some very large artery was torn across; secondary hemorrhage was, however, very common.

The new projectile neither bruises an artery nor pushes it aside. There is no evidence that an artery is ever pushed aside and thus escapes injury, and, except at a very short range, the bullet never entirely divides one of considerable size. A large vessel in the course of the wound of exit is extensively lacerated after the bullet has previously passed through bone, but otherwise the wounds are incised in aspect. Frequently a part of the vessel-wall is cut as if punched out. This incomplete division renders a spontaneous arrest of hemorrhage extremely difficult, and therefore fatal primary hemorrhages will be more frequent in the future than in the past. The most important question is, how far the injuries inflicted by the new projectile will be more amenable to successful treatment. Volkmann asserted that the subcutaneous character of gunshot injuries of bones and joints made them much less dangerous than compound fractures produced by other causes. Pirogoff was astonished by the easy healing of the wounds caused by the small Circassian copper bullet.

MacCormac has received favorable accounts of the character of the wounds caused by the Lee-Metford bullet from Burden. The wounds through the soft tissues were practically incised, with very little bruising, and they quickly healed, and clean, punched-out holes with little splintering were found in the bones, and in no case was there any explosive action. It is difficult to estimate the extent of gunshot injury to the bone when it is covered by the soft parts. In future the rule of practice in gunshot wound of the diaphysis will be conservation of the limb. If the exit-wound be large and ragged and important vessels and nerves are damaged, amputation will be demanded, but this necessity will depend upon the associated injury to nerves and vessels, and not on the extent of the fracture of the bone. If the epiphyseal extremity is the part injured, the conditions are also favorable, even when the adjacent joint is involved. In future, good hope of success may be entertained of saving life and limb without operative interference in similar cases.

When the bullet passes through the lungs, it leaves a cylindrical tract that is smaller than the bullet. The tissues are but little contused and splinters of rib are seldom taken in. If the bullet strikes transversely and carries fragments of rib with it, or injures a large vessel or bronchus, of course the damage is most serious. In many cases diagnosis is only arrived at by the positions of the wounds of entrance and exit. In many cases there are subcutaneous emphysema, hemoptysis, dyspnea, and pneumothorax or hemothorax. When death occurs, it is due to injury of the great vessels or bronchi at the root of the lung.

MacCormac says that, excluding suicide, the mortality in these cases is 12.5%. Unfortunately, gunshot wounds of the brain and abdominal cavity are as fatal as before. In the Franco-Prussian War 10% of the total number of gunshot wounds were of the head, but only half of these were perforating. In future every bullet which hits the head, even up to 2000 yd. and more, will fracture it extensively, and at 3000 yd. the bullet will probably enter it and lodge. These cases almost invariably die immediately from injury to brain-tissue and shock, or die from hemorrhage and subsequent inflammation. To these the ordinary rules of practice must be applied.

In gunshot wounds of the abdomen nothing is of any avail but very early celiotomy, for after the onset of peritonitis operation will come too late.

MacCormac's conclusions are that in future wars many wounds will be less severe and more amenable to treatment than in the past. There will be a very great number of severe injuries, because of the long range and penetrating power which enable the projectile to traverse the bodies of several individuals in line, including bones, and to inflict serious wounds at a distance of 3000 or 4000 yd. It is impossible to say what the proportion between these two is likely to be. At nearer range the explosive effects will be about the same as before, but at long range the small bullet track, the slight external orifice, and the very moderate degree of comminution and fissuring of the bone will be of great advantage. These will form the bulk of gunshot injuries of the future, for it would seem impossible with magazine quick-firing rifles to maintain a

contest at close quarters without speedy annihilation of both parties. The number wounded in proportion to the number engaged will be greater.

Sir William thinks that the next great war will be more destructive to human life than any of its predecessors, and that the number of injuries, and often the severity of injuries, will be increased, but that very many cases will remain less severe and more capable of successful treatment and less likely to entail future disablement. It is the constant effort of surgery to provide antiseptic protection in an effective form in time of war; and the medical organization during England's last war with Egypt was so complete in this respect that not a single case of infective wound-disease occurred in the whole campaign. Some form of antiseptic occlusion will prove most generally applicable. The small wounds of entrance and exit render this plan comparatively easy and lessen considerably the dangers of infection. The fact that a bullet is lodged is no longer sufficient indication *per se* to attempt its removal: it is better to employ the eye rather than the hand at a first dressing-station, as Fischer has well said.[1]

Knaggs[2] reports a case of **gunshot injury produced by the Lee-Metford rifle.** The rifle was discharged at a distance of about 10 yd. A small wound was found which was somewhat depressed on the left side between the 9th and 10th ribs. It was surrounded by a contused ring $\frac{1}{8}$ in. deep. The wound of exit was on a level with the 3d lumbar vertebra, and 1 in. to the right of the spine; it was about the same diameter as the wound of entrance, and presented three everted triangular flaps. There was no contusion about it and no external hemorrhage. The patient died in a few hours, and postmortem examination showed that the spleen had been torn by the passage of the bullet. The substance of the spleen was exposed and protruded from the capsule. In other words, the wound of the spleen was distinctly explosive. The jejunum was injured, and two elliptical pieces of bowel were destroyed, amounting to half the diameter of the gut. The edges of the wounds were contused, and blood was extravasated between the layers of the mesentery. The psoas muscle on the left side was perforated opposite the 3d lumbar vertebra; the opening in the muscle was about $\frac{1}{2}$ in. in diameter. Surgeon-lieutenant Jay Gould[3] makes some observations upon the Lee-Metford bullet obtained from a study of cases of those injured by the actions during the Chitral expeditions. This paper has been commented on by Sir William

[1] *Gunshot Wounds in the Transvaal.*—The recent crisis in the Transvaal, as shown by the report of Prof. Liebmann, secretary-general of the St. John Ambulance Association in South Africa, is responsible for about 40 cases of gunshot wound. The report chronicles some unique data for students interested in this class of injuries, of which the following is a summary: Wounds made by the Lee-Metford rifle were much cleaner and healed more quickly than injuries inflicted by any other weapon. One burgher, shot through the lungs, left the hospital convalescent the next day, and another, shot through the head, lived for ten days afterward. The Lee-Metford bullet completely shattered bone it came in contact with, and did little injury where the wound was confined to the fleshy parts, while the Martini-rifle bullet made large, jagged, ugly wounds with bad apertures of entrance and worse of exit. The Lee-Metford is, therefore, conceded to be inferior to the Martini rifle (Am. Med.-Surg. Bull., Apr. 25, 1896).

[2] Brit. Med. Jour., July 20, 1895. [3] Ibid.

MacCormac in a previous article, and contains valuable conclusions. The body of the 3d lumbar vertebra had been struck, and a piece of bone had been destroyed about ½ in. in depth immediately below the intervertebral disk. From the lower angle of this cavity to the inferior surface of the angle of the vertebra the bullet had passed across the spinal canal, and then split the right lamina from its junction with the spine through the inferior articular process. One would have expected that the discharge of the modern projectile at such a close range would have produced more severe effects with great comminution of the hard parts than was found in this case. We would have expected the wound of exit to have been of much greater extent. This case goes to prove the contention of Prof. Horsley, that the destructive effects of bullets with high velocity vary directly as the viscosity of the body.

Girard[1] of the U. S. Army makes a report of the effects of the **Krag-Jorgensen rifle-wounds** upon the skull of the living, and maintains that it is a fallacy to consider that the modern rifle inflicts humane injuries. The case was a military convict who attempted to escape, and who was shot through the head. Girard saw the man a few minutes after he was shot. He was entirely unconscious, and death was obviously a question of a few minutes. A thorough examination revealed two bullet wounds—the wound of entrance in the upper occipital region, the wound of exit in the forehead. The sentry had fired at a distance of 10 feet, and the bullet after passing through the man's skull went through a tree 8 in. in diameter and buried itself 2 ft. in the ground. The man died in half an hour. The postmortem observation showed that the bullet had an "explosive" effect.

A **case of gunshot wound** is reported by Walter Reid[2] of the Royal Naval Hospital, Haslar, illustrating the diagnosis of metallic substances in the body by the electric probe. On probing the wound the instrument came into contact with a rough material, but could be passed beyond it into the abdominal cavity. The surgeon proposed to make an exploratory incision, but the patient objected to any further operations of the sort being done for the present. Nélaton's probe gave no certain indication, and when the points of a pair of electrical forceps were brought down upon the hard surface the magnetic needle was not deflected. Lt. Bacon of the Naval Torpedo School at Portsmouth decided that the claws of the forceps were not sharp enough to penetrate any nonconducting film arising from oxidation or other chemical combination upon the surface of the metal. He devised a probe consisting of two sharp needles which were insulated over each other, the points being exposed ⅛ in. apart. Wires led to a single bichromate cell and galvanometer. When these needles were brought firmly down upon the foreign body the magnetic needle was at once deflected. The patient was now convinced of the necessity of operation, and a piece of steel 1¼ in. long and ¾ in. in diameter was removed. It lay in the abdominal cavity, and in this cavity the surgeon could place his finger. The patient made a good recovery. It is obvious that there is a necessity to have sharp points upon electrical probes, and a

[1] Jour. Am. Med. Assoc., Oct. 9, 1895. [2] Brit. Med. Jour., Jan. 4, 1896.

fair pressure applied in working them, so that if no deflection is obtained, it may be confidently asserted that no metal has been touched.

Wilson [1] of Oregon reports a remarkable case in which there were **multiple gunshot wounds of the intestine;** there was a resection of 43 inches of ileum and anastomosis with Murphy button; the patient recovered.

Lilienthal [2] suggests a **bullet-probe and bullet-forceps** new in principle. The instrument is founded upon the fact that when two dissimilar metals—for instance, silver and copper coin—are held simultaneously in the mouth, one upon the tongue and one beneath it, there is a distinct and unmistakable electrical sensation, together with a strong metallic taste, which is perceived as soon as the metals are brought in contact, and not before. The sensation is continuous as long as one metal touches the other. Sensitive individuals may even see a slight flash of light. His apparatus consists of a mouth-piece made up of two metals which fit at the sides of the tongue, one of copper and one of zinc, completely insulated from each other by being set in a hard-rubber frame. Two insulated wires are connected, one with the zinc plate, the other with the copper. The probe itself is a metal tube containing the continuations of the wires just mentioned. The tip of the probe is isolated from the shank by a hard-rubber washer. The tip consists of an even number of bright metallic pieces separated from each other by thin hard rubber or similar material, and connected with the insulated wires in the probe. The hidden wires are firmly fixed to a plug into one end of the shank, so that they cannot be drawn tight. From this plug come two connecting pins to which the wires from the mouth-piece are to be attached. When the operator holds the mouth-piece in position by closing his teeth upon it, nothing is perceived until the electrodes in the probe-end touch metal, when an immediate, continuous, and unmistakable sensation, together with metallic taste, ensues. No contact except a metallic one will produce this phenomenon. The current engendered by the mouth-battery is too weak to be appreciated until this battery is short-circuited.

Lilienthal gives the following rule for improvising this probe: Cut both ends off a soft catheter. Take two pieces of wire and insulate them to within an inch of their ends by wrapping round each wire a layer of gutta-percha tissue and then warming, or even winding the wire with adhesive plaster. Run the wires through the catheter, allowing two ends to project at the proximal end. Two short ones, each bent on itself so that a smooth loop of wire may present, instead of a rough cut, should project at the distal end. The wires are fixed at each end by drops of sealing-wax. The long ends of the wire are now wound tightly around two coins, the one around a copper, the other around a silver coin, previously removing as much as necessary of the gutta-percha insulation. Entirely cover these connections with sealing-wax, and this probe will now work well enough for an emergency.

Lilienthal has also devised a bullet-extractor. He takes one blade of an American bullet-extractor which is insulated by hard rubber to within a tenth of an inch of its tip. An ivory peg is used instead of the usual steel lock-screw or lock-peg. A connecting pin is soldered to each handle with the connecting

[1] Ann. of Surg., Sept., 1895. [2] Ibid., May, 1896.

wires, which go to the mouth-piece, and when the forceps holds the bullet the operator instantly and constantly perceives the mouth-phenomenon.

Fowler[1] has made an elaborate study upon the **localization and removal of missiles from the cranial cavity.** He tells us that the traumatism of the bullet differs from that arising from any other cause, for the reason that, no matter how slight and apparently simple the injury, the element of concussion always enters into the case, and is to be added to the other existing symptoms. We cannot have a bullet injury of the head without concussion, and the concussion caused by firearms is far greater than that produced by any other means. The mere fact that a bullet strikes the head causes concussion; it does not need to enter it. Hence the primary symptoms of bullet-traumatism are the symptoms of general shock. The immediate effects of all bullet-injuries of the skull are manifested upon the medulla. In the concussion the pneumogastric center and the inspiratory center are either inhibited or paralyzed, and those portions of the brain that have localizing functions fail to give evidence of their specific functions until the concussion has passed off. The extraordinarily rapid rate with which the function of the respiratory center in the medulla oblongata is inhibited or fails altogether is peculiar to gunshot injuries of the head. There is reason to believe that the prompt use of artificial respiration may restore these functions in even the most apparently hopeless cases, and that no person should be pronounced dead from a bullet-injury to the head, other things being regarded, unless artificial respiration has been tried and failed. The heart's action may be either retarded, as in moderate concussion, or accelerated, as in intense concussion. The secondary symptoms of gunshot wounds of the head are very varied and misleading, and they may be positively absent even up to the time of death. The first point a surgeon must determine when a fracture is found, but there is no evidence of perforation, is whether or not the ball has passed through the bone between the depressed fragment and adjoining sound bone, the former springing back from its natural elasticity after the bullet has entered the cranial cavity. Surgeons will remember Von Bergmann's case, in which there was a fissure at the point of entrance, and yet on autopsy a bullet was found in the brain. Another fallacy is that we may find an opening of exit in cases of complete penetration. This shows that the bullet should always be closely inspected when recovered. Great difficulties may be encountered when the bullet enters from the cavity of the mouth. Here there should be an immediate search of the cavity of the skull to determine if there is any projecting area of the surface or evidence of fracture. If there is no such damage or sign of fracture, the surgeon must try and determine if the bullet could have lodged in the nasal fossa or one of the axillary sinuses. There is another fallacy to be borne in mind, that the patient may have simultaneously received other injuries, and that these other injuries, and not the bullet-wound, give rise to the cerebral symptoms. Gunshot wounds of the face may enter the cranium or may stop short of it. When we have decided that a bullet has perforated the skull, we must next determine

[1] Ann. of Surg., Nov., 1895.

if it has perforated the dura. In order to do this remove a button of bone by the trephine when the vault is involved, or enlarge the opening in the bone by the chisel or mallet or cutting forceps. Of course all of these procedures are done with the most rigid adherence to accepted theories. The bullet may be found upon the dura or between the dura and the inner table of the skull at the site of the wound or at a point remote from the original point of entry. This may occur in the case of a spent ball or one which has lost its projectile force immediately after entering the skull. The dura may be injured by splintered fragments of the inner table, whereas the bullet itself can remain extradural. The ball may pass but a short distance into the brain-substance, and be felt by the surgeon's finger after enlarging the opening in the dura. In cases in which the bullet passes but a short distance into the cerebral mass splintering of the internal table seems to be greater than when we have high velocity. When both tables are broken the inner table suffers most. This is not due to greater brittleness of the inner table, as used to be taught, but is according to Teevan's law—that is, that fracture commences in the line of extension rather than in the line of compression. We know for a fact that when the inner table receives the force of a bullet first, the outer table is the one which is most extensively broken. The ball may be discovered within the dura and just below the point of entry. When the ball does not lie just below the point of entry, we have to consider the question of the direction which the projectile may have taken in penetrating the cerebral mass. A ball may be lodged in the substance of the hemisphere. It may cross the hemispheres and lodge in the opposite walls of the skull, and it may be without sufficient force to penetrate this wall and turn back again, and after a recurrent course of from 1 to 3 in. may lodge in the brain-substance or the ball may pass clear through. The probable position of the ball is based on the position of the weapon at the time of shooting. The surgeon should thoroughly inspect the opposite side of the head to see if there is a perceptible bulging or evidence of fracture, but even the exact primary course of the bullet is always uncertain, and the difficulty of diagnosis is aggravated by the fact that a ball may be deflected from the opposite wall and lodge at a remote point. In 1884, Flührer reported a case in which he trephined at the point of impact against the opposite wall in order to trace the course of the deflected ball.

Ruth disagrees with Flührer's statement that the bullet may be deflected after striking the opposite wall, and he asserts that a ball will rebound only when it is flattened at least one-third, and that a velocity that could produce a third flattening would inevitably penetrate the skull. According to this last observer, if the ball strikes the surface at a right angle or within 15° of a right angle, and does not penetrate, it will not rebound, but will lodge at or near the point of impact. Ruth says that when deflection does occur it is almost invariably at angles of more than 90° to the angle of coincidence. In cases of complete penetration the first attempts to search for the bullet will be made by means of the finger. This may discover splinters of bone even if the ball is not located, and these splinters are at once removed. If the surgeon fails to

find the missile in this manner, he considers the question of probing the brain. No sharp-pointed instrument or pocket-case probe should be used. Whatever material the probe is made of, it should have a spherical or olive-tip mounted upon a slender shaft in order to lessen friction in its contact with the collapsed bullet-track. We should know the caliber of the weapon in order to be able to select a proper sized probe. A bullet of 32 caliber requires a tip $\frac{1}{4}$ in. in diameter, and the bullet-track of one of the smaller weapons should be explored by a probe $\frac{3}{16}$ in. in diameter. The amount of force to be used varies with the size of the tip and with the nature of the injury. In small tips we must use less force than in large tips. Ruth thinks we should employ a device whereby we could obtain the exact pressure in ounces while using the probe. If possible we depend on gravity alone to carry the instrument through the bullet-track.

Fowler has devised an instrument after the plan of Ruth which he calls the **graduated-pressure brain-probe.** He uses it in the horizontal position in order that the weight of the instrument and gravity may be eliminated from consideration. As long as the pressure made is within the limits of the spring, as shown by the indicator and scale, the probe is in the bullet-track, but as soon as the tip leaves the path of the missile this will be shown by an amount of force necessary to propel it forward. Contact with the bullet or fragment is announced by the characteristic click in the telephonic receiver applied to the ear. Attempts have been made to locate the exact position of the bullet in its relation to the surface, and to indicate the exact point at which a counter-opening may be made by the trephine. Morgan devised such an instrument. For detecting a bullet Nélaton's probe is far inferior to Girdner's probe. Search for the bullet by a long slender and blunt needle passed through the cerebral substance, avoiding the sinus of the dura and the medulla, has been employed, but without success. The large number of cases in which recovery without operation has followed bullet-wounds of the cranial cavity, and the supposed comparative infrequency of recovery in cases in which operative interference is instituted, have thrown doubt upon the justifiability of surgical intervention, and differences of opinion existing as to the advisability of doing more than trephining for the removal of splinters of bone and the bullet if it is within easy reach.

Hahn has given statistics of cases in which operation was performed and bullets removed, and those in which it was not practised. The introduction of aseptic and antiseptic surgery has modified results. Of 60 reported cases of operation, 40 died and 20% recovered. There are really more deaths in 20 nonoperative cases than are usually mentioned, because of late secondary effects.

Fowler then presents the divergent views upon the advisability of operation. He advocates operation in most instances, although he is inclined to adhere to the dicta of Von Bergmann, who does not operate when symptoms are absent, and does operate when there are important and severe symptoms of irritation. The author discusses the details of operating, the mode of arresting hemorrhage, and the after-treatment. The entire paper is of extreme value, and its conclusions are drawn from the literature of the subject and from cases which the author has had under his own charge.

OBSTETRICS.

By BARTON COOKE HIRST, M. D., and W. A. NEWMAN DORLAND, M. D.,

OF PHILADELPHIA.

The Chief Features of the Year's Work.—In obstetric circles among the points of more than usual interest one of the principal has been the application of Dührssen's and Mackenrodt's vaginal celiotomy in the treatment of extrauterine gestation. This is a recent suggestion, originating, as might be supposed, among the advocates of this method of pelvic surgery, who claim for it a diminished amount of shock and a lessened mortality. While it is interesting to note the performance of this operation for the relief of such a condition, it is far too early as yet to state what may be its possible outcome, but the increased danger of sepsis and the greater mechanical difficulty of the vaginal method as compared to abdominal section are strong objections to its general adoption. Symphysiotomy, after passing through a phenomenal tidal-wave of popularity, is now finding its proper level as a valuable conservative operation, of, however, but limited applicability, having an appreciable mortality and attended with a fair proportion of unpleasant complications and sequelæ. That it is undoubtedly preferable to craniotomy upon a living and healthy child is universally conceded, but there is a warrantable uncertainty, all things being carefully weighed, as to its superiority to Cesarean section. Especial commendation is due Barbour of Edinburgh for his admirable studies upon the mechanism of labor as revealed by frozen sections of women dying during the process of parturition. The results thus obtained from an examination of 23 cases must very truly be classed among the most important contributions made during the last half century to the science of obstetrics. Through these investigations more accurate information has been obtained as to the process of placental separation and the arrest of postpartum hemorrhage, as well as of the various stages of fetal and placental expulsion. Malignant deciduoma and its intimate relationship with a preexisting cystic degeneration of the chorion is a subject of growing interest, and one that, next to symphysiotomy and labor subsequent to anterior uterine fixation, has commanded the largest share of obstetric study during the past year. The relationship of this neoplasm to the sarcomata may be said to be already fully established, and the frequency with which the condition, rare at the best, has followed a previous hydatidiform mole must be regarded as more than a mere coincidence. Fränkel's microscopic investiga-

tions have largely contributed to our knowledge of the pathology of the disease, and this, together with the accumulation of clinical records, combines to establish its morbific entity. The serum-treatment of sepsis is a novel procedure which is entirely too new to criticise safely. While, according to some observers, beneficial results promptly follow the subcutaneous exhibition of the antitoxic serum, in the hands of others equally as able it has signally failed; and it is to be feared that it will follow the beaten path already taken by tuberculin and the other antitoxic serums. The future results of this mode of treatment must, however, be closely studied in order to arrive at any positive conclusion as to its efficacy in puerperal sepsis. Finally, to the numerous causes of maternal dystocia already existing, and which perplex the obstetrician, must be added one other—namely, that arising from the various forms of anterior fixation of the uterus performed for the relief of uterine retrodisplacements and prolapse. The current literature is teeming with reports of difficulties arising during gestation and labor directly consequent upon the results of these operations, and the very practical and serious question presents itself, Which is the greater evil—the gynecologic condition or the obstetric difficulties consequent upon its *improper* method of correction? We term the method "improper," not because of the idea involved, for anterior fixation for the relief of these displacements is eminently rational in every sense of the word, but because we believe that the fixation has not been carried out in an absolutely proper manner. The idea is correct, but the technic is imperfect. This can only be demonstrated however, by time and an investigation as to the relative frequency of dystocia after the various forms of anterior fixation.

PRELIMINARY AND GENERAL CONSIDERATIONS.

Obstetric Education.—[The demand for a more thorough obstetric education is increasing year by year, in England as well as in the United States, notwithstanding the fact that there still lingers in the British General Medical Council some of the traditional hatred for the practice of midwifery.] Rentoul[1] deplores the condition of affairs, and makes the alarming statement that even as late as 1893, in England and Wales, of a total of deaths of 569,958 persons, 5950 were women who died from puerperal fever and the other accidents of childbirth; that is, at least 1 death in every 95 of the total deaths was that of a woman in childbirth. [In the best of hands in the United States the mortality of childbirth has now been reduced to slightly under 1%.] He further declares that Duncan has shown that 1 in every 15 women in first confinement dies, thus making the maternal mortality much higher than that following major surgical operations. He believes that the medical student should personally conduct, under the direct supervision of a registered physician, at least 30 labors before a diploma be granted him. Grothan[2] writes in a similar strain, and especially decries the evil practices of the so-called midwives, who have no knowledge of even a normal presentation, and are grossly ignorant of all the dangers that surround the lying-in

[1] Brit. Med. Jour., Nov. 23, 1895.

[2] Wilkinson's Clinic, Sept., 1895.

woman and her infant. In New York City, in 1891, 24,123 birth-returns were made by midwives, this being nearly half of the whole birth-returns. The largest proportion of stillbirths and maternal fatalities were under the care of midwives. Often men of true science and ability are obliged by popular opinion to stand aside and view the malpractice of the ignorant midwife who undertakes the care of two lives with all their perils. [It is to the medical profession that we must look for a reformation, and, fortunately, the protestations of the past few years are beginning to bear fruit in the form of stricter regulations and laws of registration, and in an awakening interest in the science of obstetrics in medical colleges and among medical students.]

Material of Obstetric Instrument-Cases.—Von Herff[1] calls attention to the utility of aluminum as a material in a case for obstetric instruments. The lightness of the material makes it possible to construct a case sufficiently large to carry the forceps and other instruments, and in which they can be sterilized without taking them from their position. The size of the forceps has rendered other cases too heavy to be conveniently carried.

THE PHYSIOLOGY OF PREGNANCY.

Sterility.—Graefe[2] of Halle and Kleinwächter[3] have investigated the causes of sterility, and both have concluded that gonorrhea does not play an active causative role, as is generally supposed. In 648 cases of sterility Kleinwächter found but 80 in which the sterility could be ascribed with certainty to previous gonorrhea; in 12 of these the husband was known to have had gonorrhea. This gives a percentage of but 13 in which sterility in women can be ascribed to that cause; and Kleinwächter believes that even this estimate is too high, as his patients were of the lowest classes, in which such a cause would operate most frequently; $76\frac{23}{100}\%$ of his cases had married before the age of 21, and he ascribes the condition of sterility to this early marriage. In 14 cases malformations of the sexual organs were present. In 31 cases some constitutional condition on the part of the husband was the disturbing element; $50\frac{77}{100}\%$ of the patients suffered from dysmenorrhea, but Kleinwächter holds that no relation exists between dysmenorrhea and sterility. Graefe enumerates the causes of sterility as follows: 1. Anomalies of the hymen or malformations of the genital tract; this includes a very large vagina, which permits the escape of the semen immediately after coitus; 2. Vaginismus; 3. Excessive acid reaction of the vaginal mucus, which causes the spermatozoa to lose the power of motion; 4. Narrow external or internal os, anteflexion, retroflexion, endometritis, gonorrhea (especially with involvement of the adnexa), and neoplasms; 5. Constitutional diseases, as tuberculosis, syphilis, chlorosis, and obesity. He believes that in half of the cases the trouble is due to some defect in the male. Only 8 of Kleinwächter's cases were cured by appropriate treatment. Electricity failed signally in every instance. In connection with this subject it would be well to note that during

[1] Centralbl. f. Gynäk., No. 39, 1895.

[2] Ibid., No. 49, 1895.

[3] Zeit. f. Geburtsh. u. Gynäk., 1895, Bd. xxxiii. H. 2.

recent years the birth-rate per thousand population has been diminishing in proportion to the population in most civilized countries, as will be seen by reference to the following table, taken from the Canadian Practitioner for July, 1895:

Country.	1880.	1890.
United States	36.0	30.7
England and Wales	34.2	30.2
Scotland	33.6	30.3
Ireland	24.7	22.3
France	24.5	21.8
Belgium	31.1	28.7
German Empire	37.6	34.7
Austria	38.0	36.7
Switzerland	29.6	26.6
Denmark	31.8	30.6
Norway	30.7	30.0
Netherlands	35.5	32.9

[That there does exist some occult relationship between sterility and increasing civilization there can be no doubt, and in this relationship doubtless will be found the solution to the Malthusian problem. It would be a matter of much interest to determine accurately why there are fewer births among civilized people than among the aborigines. Increased sexual torpidity in some instances, in others an exhaustion of the sexual power from excesses, and in others the ravages of venereal diseases, may account for the condition.]

Conception and Fecundity.—[The remarkable vitality of human spermatozoa is a well-recognized fact. Various authorities state that the spermatozoa may continue to move during from 24 to 84 hours after death in the fluids of the seminal tract. Outside the body the movement of the spermatozoa has been observed for 72 hours by Hofmann and Mantegazza at a suitable temperature.] Piersoll[1] now remarks that at a temperature of 8.5° C. a few of the elements showed movement after being kept for 9 days. [These facts prove still more forcibly that spermatozoa may long retain their vitality in the female generative tract, and this must command in future due consideration in connection with certain medico-legal subjects.]

A question of more than ordinary interest, and one that has excited considerable controversy, is that which concerns the procreation of sex at will. Petrus Truong Vinhky of Annam, in a letter quoted by Stephenson,[2] claims to have evolved a theory upon which this power may be acquired. His plan of action is founded on the "system known as dualism, or the *bina principia* (*âm et duong*), male and female principles (*principes opposés*), alternating and constituent of the life of human beings, as well as of the existence of things in nature. In all that is we must recognize the control of definite laws (conditions of existence). Moreover, the procreation of male and female is one of the fundamental bases of terrestrial life." "Furthermore, physicians all recognize that there are in the ovary of woman both male and female germs

[1] New Orl. M. and S. Jour., July, 1895. [2] Boston M. and S. Jour., Mar. 26, 1896.

(potentially?). These two opposite elements should act alternately. Knowing, then, the beginning and the duration of this alternate action, our course of procedure becomes plain." On such a basis as the foregoing Vinhky succeeded perfectly in alternating son and daughter in five successive pregnancies, and then, desiring sons only, he engendered such. He intends to demonstrate this theory in a series of lectures at Paris during 1900.

Longfellow[1] reports a case of impregnation of a single woman from semen deposited on the vulva without vaginal impenetration. Examination revealed advanced pregnancy, with, however, a virginal condition of the vulva, a thin intact hymen, and a vagina so small as to scarcely admit the finger. Duhousset[2] reports an impregnation of one sexual pervert female by another, who had married, but who continued her relations with the other. The unmarried female had an enlarged clitoris by which coitus was performed; much to her astonishment, she became pregnant, when the married pervert admitted that she had indulged with her friend immediately after having had coitus with her husband. Gleaves[3] adds another case of precocious motherhood to those already on record. This girl gave birth to a well-formed child when at the age of 10 years and 2 months. She lacked the development of a woman, although she had menstruated regularly from the age of 5 years. The labor was short and uneventful, and 2 hours afterward the girl wished to get up and dress. The mammary glands were undeveloped, and there was no secretion of milk. The infant lived for a week.

The Female Pelvis in Primitive Races.—Stratz[4] investigated a series of cases in Java to test the accuracy of certain theories in respect to the relative characters of the pelvis in European and in barbarian or semicivilized women. Faayer of Leyden declared 20 years ago that the Javanese pelvis was unusually round at the inlet. Stratz reminds obstetricians that this theory was based on the examination of a few macerated pelves. He therefore measured a large number of pelves of Javanese women living up country. Two races were included in his series, the more primitive being darker, more slender, and smaller. The measurements showed little or no difference more than could be explained by the small general proportions of one of the races. The same may be said of the difference between the average Javanese and European pelvis. [As it happens, however, the theory of Faayer seems substantially correct, the transverse measurement of the Javanese pelvis being, on an average, relatively small. The obstetric teacher should also bear in mind that Stratz found plenty of contracted pelves among these primitive women, who, escaping the evils of civilization, do not enjoy its benefits. This would seem to weigh against the generally accepted theory that with advancing civilization, with its improper mode of dressing, pelvic contraction is increasing in pregnancy.]

The Position of the Fetus in Utero.—Pajot's law of accommodation,

[1] Buffalo Med. Jour., Oct., 1895.
[2] Ibid., Oct., 1895.
[3] Med. Rec., No. 1306, p. 715, 1895.
[4] Nederl. tijdschr. v. Verlosk. en Gynecol., 6th year, part 1, 1895.

while generally accepted as the probable cause of the common cephalic presentation of the fetus, is not universally so. Davidson[1] thinks that Simpson's theory is pretty doubtful yet, and believes that the ovoid shape of the uterus has little effect upon the presentation of the fetus, and, indeed, that the uterus is compelled by the position of the fetus to assume that shape. Basing his idea upon the observations of the larvæ of the hymenoptera, which always turn their heads to the natural outlet, Davidson concludes that both the theories of "gravitation" and "adaptive action" are inadequate. In the human subject the mothers whose fetuses presented otherwise than by the head would, in the savage state, gradually die out. "The cephalic presentation, whether at first an accident or an inheritance from the lower forms of life, as seems the more probable, is instinctive in the fetus now." Davidson therefore thinks that the cephalic presentation has become the normal one for the higher mammalia by a process of natural selection. Cameron[2] advances an entirely new theory as to the longitudinal position of the fetus *in utero*. He believes that the child invariably assumes a definite posture in its relation, not to the pelvis, as has hitherto been assumed, but to the site of the placenta. His experience in Cesarean section has shown him that in dorsoposterior positions the placenta is attached upon the anterior wall, while in dorsoanterior positions the placenta is upon the posterior wall. Thus, in the first cranial position (L. O. A.) the placenta will be found upon the posterior wall, and somewhat to the right side. In the second cranial position (R. O. A.) the placenta will be upon the posterior wall, and somewhat to the left side. In the third cranial position (R. O. P.) the placenta will be upon the anterior wall, and somewhat to the left side. In the fourth cranial position (L. O. P.) the placenta will be upon the anterior wall, and somewhat to the right side. The fetus and placenta will be found in the same relation in the various pelvic positions. This being the case, it may be readily understood how this arrangement favors the well-being of the fetus during labor, as then, during a uterine contraction, the back of the fetus can apply itself to the uterine wall with advantage, whereas if the placenta intervened asphyxia would result, more especially after the membranes had ruptured. The relative frequency of the four positions of the vertex are as follows: First position (L. O. A.), 67%; second position (R. O. A.), 10%; third position (R. O. P.), 20%; fourth position (L. O. P.), 3%. Therefore, in 77% of the cases the placenta would be upon the posterior wall, and in 23% of the cases upon the anterior wall. [The early development of the placenta and membranes would be a strong point in the support of this theory.]

The Heart in Pregnancy.—Handfield-Jones[3] in a series of lectures delivered before the Harveian Society has made an exhaustive study of the varying conditions of the heart during pregnancy, parturition, and the puerperium. With regard to the *bruit de soufflet* recognized by Larcher, Beau, and others, and considered by them to be a nearly constant concomitant and index

[1] Glasgow Med. Jour., June, 1895. [2] Brit. Med. Jour., Feb. 29, 1896.
[3] Lancet, Jan. 18, 1896.

of left-ventricle hypertrophy, he records a contrary experience. In about 50 multiparæ examined by him during the 7th and 8th months he has heard this bruit only some 5 or 6 times. He has limited his observations to strong, healthy mothers, in whom one might reasonably expect hemic bruits to be absent. He does not deny, however, that a bruit is *occasionally* present in cases of pure left-ventricle hypertrophy. He also states that though occasionally left ventricular hypertrophy may not be very pronounced at the end of pregnancy, especially in feeble or poorly developed women, yet in the vast majority of healthy subjects this increase in thickness of the wall of the left ventricle is always present. He has obtained confirmatory evidence of this cardiac hypertrophy in pregnancy by watching the effect of rapidly growing abdominal tumors on the heart. He has found that in patients in whom abdominal tumors (of a size to reach nearly up to the xiphoid cartilage) have been removed, and examination of the chest has been made within a month after the operation, the heart's apex may often be found displaced downward and outward and the area of cardiac dulness increased. Again, in elderly women, should an abdominal tumor grow rapidly, heart-failure may be a prominent symptom at an early date, as the advanced age of the patient renders the development of compensatory hypertrophy to meet the rapidly increasing work less probable. He has made numerous observations with the sphygmograph to ascertain, as far as possible, the absence or presence of evidence of increased arterial tension in women advanced to nearly the full term of pregnancy, and in all instances in which the patient has been a strong, healthy woman he has found it present.

The Course of Pregnancy, Labor, and the Puerperium in Young Primiparæ.—From 260 cases of pregnancy in very young women treated in the clinic at Marburg during the past 18 years, Spitta[1] concludes that the gestation is generally not associated with more annoying symptoms than in older women. Labor usually takes place before the end of 40 weeks, and is apt to be long and tedious, partly on account of weakness of the labor-pains and partly owing to the small size of the undeveloped pelvis. Dystocia, due to the bony pelvis, is much more uncommon than obstruction from the soft parts, which latter are apt to be more or less lacerated during the labor. Postpartum hemorrhage, fever, and sore breasts are of frequent occurrence. Forceps are indicated oftener than in older primiparæ. The mortality for both mother and child seems to be but little increased.

Decidual Formation.—F. Nordmann[2] has given his conclusions, founded upon careful macroscopic and microscopic examinations of 5 gravid uteri, in regard to the oft-mooted question as to whether the lower segment of the uterus contains uterine or cervical mucosa, and whether the cervical mucosa undergoes decidual changes. He believes, first, that the lower segment belongs, both in its muscular structure and in the character of its mucosa, to the body of the uterus, its mucosa acting in the same manner as that of the body in the development of the decidua; secondly, the cervical mucosa takes part

[1] Centralbl. f. Gynäk., No. 51, 1895.

[2] Ibid., No. 27, 1895.

at no time during pregnancy in the formation of the decidua, the cervix itself normally remaining closed practically throughout this period; thirdly, the internal os is situated where the muscular structure of the body suddenly diminishes in thickness. The latter sends out only single muscular fibers in and around the fascia surrounding the cervix. At this spot the decidua ends and the unchanged cervical mucosa begins.

The Placenta and Placental Circulation.—The development and normal structure of the human placenta was the subject of a paper read by Eden before the Obstetrical Society of London, June 5, 1895. The placenta consists of 2 portions, a fetal and a maternal, the fetal being developed from the external fetal envelop or chorion. At the end of the second week the chorion is covered with villi, the reflexa has closed over the ovum, and the tips of the villi are loosely imbedded in it. The fetal and maternal vessels are thus brought into close relation, and the general arrangement represents a simple type of diffused placenta. The development of the discoidal placenta merely consists in the specialization of a part of the chorion. The placental chorion consists of 3 sets of structures: (1) a covering of epithelium, (2) a connective-tissue stroma, and (3) blood-vessels. The chorionic epithelium consists of two layers; the superficial layer or trophoblast represents the fetal epiblast, and is the more important of the two. By a process of proliferation buds are formed from the trophoblast, which develop into new villi. The stroma consists of a delicate reticulum of branching connective-tissue corpuscles with numerous leukocytes. The meshes of the stroma form a system of lymphatic channels that are in communication with the capillaries. The vessels of the villi are very large and numerous, and run for the most part immediately beneath the epithelium; this is an arrangement favorable to osmosis. The lymphatic system of the stroma can be artificially injected from the capillaries. In an uninjected placenta blood is often found in the stroma, so that the villi appear to be soaked with blood like a sponge. The maternal placenta is developed from the uterine mucosa. The earliest changes are a continuation of those found in menstruation, for the fertilized ovum is engrafted on the mucosa in its active phase. The development of the decidua consists of three stages. In the first stage extensive hemorrhages occur in the decidua, and decidual cells are formed in large numbers from the connective-tissue corpuscles. These changes are preparatory, and can be found in all parts of the decidua during the first months. In the second stage the chorionic villi invade the serotina and the maternal vessels are opened up, thus establishing a circulation through the intervillous spaces. The invasion of the serotina appears to be the result of the great activity of the trophoblast layer. The decidual cells also show great activity in the absorption of blood effused into the serotina. Large lacunæ are formed by the opening up of neighboring vascular and glandular channels. The changes characteristic of this stage are found at the growing margin of the placenta up to the last weeks of gestation. The third stage represents the adult stage of the serotina. All active processes have then ceased, and the serotina has undergone some amount of consolidation and

repair. The intervillous spaces are, according to Eden, made up (1) of the space existing primarily between the decidua and the chorion; (2) of spaces formed by destruction of decidual tissue; (3) of glandular and vascular channels opened up in the same way. The circulation through the intervillous spaces is not rapid, the outflow being chiefly promoted by the intermittent contractions of the uterus. The giant cells so often described in the serotina are really imbedded trophoplastic buds. The fetal and maternal structures of the placenta are firmly bound together by the attachment of numerous villi to the serotina. Owing to this firm union, separation of the placenta during labor occurs, not between the fetal and maternal layers, but through the loose cavernous layer of the serotina.

Placental Transmission.—[The transmission of certain drugs and of bacteria and their products through the fetoplacental circulation is a well-recognized fact. The demonstration of this truth is, however, of such recent date that additional confirmatory data are welcome.] Bureau[1] attended a patient who for 7 years had taken morphin, and at the time of his attendance was taking 15 gr. daily. She was in her fourth pregnancy, and spontaneously gave birth to a child with talipes of one foot. As the cord was divided Bureau collected the blood of the placenta and umbilical vessels, and in this, on chemical analysis, morphin was detected. Ricker[2] reports a case of streptococcus infection from mother to fetus in a woman 27 years of age, who died in the sixth month of pregnancy of a disease diagnosticated diphtheria. By careful bacteriologic examination the streptococcus pyogenes was the only germ found, and it was obtained in pure culture from the placenta and from the liver of the fetus. No lesion was found in the fetus. Ricker recalls a second case in which the streptococcus was found in the blood of the umbilical veins of a stillborn child whose mother died shortly afterward from the effects of a phlegmon of the arm which was present at the time of birth. In neither of these cases was any lesion of the placenta discoverable. Freund and Levy[3] record a case of intrauterine infection with the typhoid bacillus, the miscarriage taking place in the fifth month of pregnancy and during the fourth week of an attack of typhoid fever. Cultures made from the spleen and heart's blood of the fetus and from the placental blood gave numerous colonies of the bacillus of typhoid. Cultures made from the outer surface of the placenta and from the vernix caseosa were sterile. No abnormality was found in the fetus, except a somewhat enlarged and slightly softened spleen; the intestine was normal. The infecting organism entered the fetus through the blood, and caused a septicemia such as has been observed in other cases of intrauterine transmission of organisms.

It may be that the mother may be afflicted with some pathologic condition during pregnancy, not resulting fatally to the infants, but giving rise to the formation of toxins in the blood. Necessarily, such a condition must be more or less detrimental to the infant's health, and Charrin and Nobécour[4] give

[1] Jour. de Méd. de Par., Oct. 20, 1895.
[2] Centralbl. f. allg. Path. u. Anat., vi. No. 2, 1895.
[3] Berl. klin. Woch., June 27, 1895.
[4] Arch. de Physiol., No. 1, 1896.

the results of interesting observations upon such infants. It was found that whereas a healthy child increases 32 grams each day, an infant born of a tuberculous mother did not gain in weight at all, while the child of a woman who died of tubercle had increased but 4.28 grams for each day. The child of a mother who before confinement had a very extensive phlegmon gained but 5.7 grams for each day. Experiments upon animals give similar results. The healthy infant loses but a moderate amount through the organs of excretion, while, on the contrary, toxins interfere with processes of nutrition and often seem to reduce a discharge of harmful waste to a minimum.

THE DIAGNOSIS OF PREGNANCY.

The value of an external examination of the pregnant woman at varying periods of gestation is urged by E. A. Harris.[1] Much can be learned by this method that it would be otherwise impossible to ascertain, and fetal death or pelvic contraction detected in time to institute active measures and thereby prevent maternal risk or death. Benttner,[2] in practising diagnosis by external manipulation, has found of especial value a method that consists in palpating the head with the two hands of the examiner. In one manipulation both hands are turned with their backs toward the abdominal surface of the mother, and firm but gentle pressure is made to distinguish the child's neck, the hands being placed beneath the chin and occiput. By the other manipulation the hands are turned in the same way, but one hand is pressed deeply behind the pubic joint, the palmar surface turned toward the pubis, while the other hand, with its dorsum toward the abdominal wall of the mother, presses in the sulcus between the head and the trunk.

The Use of *x*-Rays.—[As may have been expected from the practical application of the Röntgen rays in surgery, efforts have been made to test their applicability to the science of obstetrics, with, however, almost negative results.]

Varnier[3] and his associates publish a Röntgen-ray picture of a uterus at $3\frac{1}{2}$ months, which had been taken from the body of a woman dying of pernicious anemia. The picture gives an indistinct outline of the fetus, which appears much darker than the surrounding contents of the uterus. Dissection of the specimen confirmed the diagnosis made from the picture. E. P. Davis[4] has instituted a series of experiments to solve the problem, Can the skeleton of the fetus be recognized by this method within the mother's womb? To ascertain the relative density of the pelvis and fetal skull to the rays the following experiment was made: The skull of an infant at term was placed in a female bony pelvis upon a sensitized plate completely sealed in a pasteboard box; the pelvis was placed in such a position that it rested upon the plate upon the tuberosities of the ischia and the coccyx, and the skull was laid obliquely in the pelvis. To secure as much definition as possible a lead diaphragm was interposed between the tube and the pelvis, and an exposure of $1\frac{1}{2}$ hours was made to test thoroughly the various positions of

[1] Ann. of Gyn. and Pæd., Feb., 1896.

[4] Am. Jour. Med. Sci., Mar., 1896.

PLATE 2.

Pelvis and fetal skull (Am. Jour. Med. Sci., Mar., 1896).

the skull and pelvis subjected to the rays. An examination of the accompanying illustration (Plate 2) shows that the greater portion of the fetal skull gives but a very faint shadow under the action of these rays, owing to the deficient ossification. The base of the skull is dark, while the temporal region scarcely gives a reaction. In marked contrast to this is seen the black coccyx, which rested upon the plate, and also the rami of the pubes and the spines of the ischia. The direct inspection of the trunk of a living fetus with the skiascope revealed the fact that the rays permeate the trunk of the new-born child with facility, but that the skeleton casts but a faint shadow. The tube was 10 in. from the body, and the exposure was 45 minutes. Reference to the accompanying illustration shows the faint outline of the ribs, a dark shadow given by the sternum and underlying spinal column, a trace of the vertebral column, dark shadows cast by the crests of the ilia upon each side, and a shadow given by the stump of umbilical cord, which lay obliquely across the body toward the right, and by the granulating tissue at the umbilicus. The attempt to secure a skiagraph of the fetus *in utero* was attended with a negative result. [Obstetrically, it would seem that in its present imperfect condition the skiascope offers but little assistance in the diagnosis of fetal position and presentation. It may be, however, that under improved conditions minor degrees of maternal pelvic contraction may be detected in early pregnancy and an appropriate course of treatment instituted at the proper time.]

THE HYGIENE OF PREGNANCY.

Diet during Pregnancy.—Eichholz[1] believes that many of the ills that accompany parturition are brought about by improper diet during pregnancy. An excess of water and of albuminous food should be avoided—water on account of its tendency to produce hydroamnion; and albumin because it favors excessive growth of the child. He prescribes the following diet: Meat once a day; green vegetables and potatoes; avoid eggs, peas, and beans, as they are too rich in albumin. Wine and beer may be taken in moderation, but no more fluid should be taken than necessary. Under this regimen the patients are active until the eve of accouchement; they do not suffer from a sensation of fulness, excessive formation of fat, thirst, or constipation; delivery is rapid and easy, even in those cases in which the previous labors have been prolonged and difficult; there is never an excess of liquor amnii; the quantity and quality of the milk are always good; the children are small, but healthy and well formed, averaging about 6 pounds in weight, and the circumference of their heads being about 33.5 cm.

PATHOLOGY OF THE FETUS AND OF THE FETAL APPENDAGES.

The Placenta.—[We cannot agree with Schoolfield[2] when, in speaking of adherent placenta, he remarks that "placental inflammation is a moot question among authors, many denying its existence." This might have been

[1] Rev. de Thér., 1895, No. 18.

[2] Am. Jour. Obst., May, 1896.

true 8, or even 5, years ago, but the observations of many eminent investigators within recent years have amply demonstrated the existence of such a condition, dependent upon syphilitic infection, a preexisting endometritis, or other pathologic condition. Certain it is that its grave sequela, adherent placenta, is a well-recognized complication in obstetric practice.] Cases of this interesting and serious condition are recorded by Schoolfield and Nyulasy.[1] Nyulasy believes that the commonest cause of placental adhesion is antecedent endometritis. In his experience the usual condition is a deposit of fibrin originating in the decidua and involving the opposed surface of the placenta, thereby forming a tough cementing bond of union between the placenta and the uterus. The situation of the adhesion is generally the fundus uteri, and union is often especially firm at the cornua about the entrances of the Fallopian tubes. For retention of fragments of the adherent organ he considers the only effective treatment to be thorough curetment of the uterus.

In a study of *tuberculosis of the human placenta* in relation to congenital tuberculosis Schmorl and Kockel[2] state that the exact method by which the tubercle bacilli passed from the mother to the fetus was not understood at the time when Birch-Hirschfeld and Schmorl reported their case of congenital tuberculosis in 1891. Lehmann's observations show that in acute miliary tuberculosis during pregnancy the placenta may be affected with tubercle as well as the other organs. The placenta, it seems, may occasionally be affected in cases of chronic pulmonary as well as acute miliary tuberculosis. Autopsies on cases of advanced pulmonary tuberculosis frequently show circumscribed foci in organs other than the lungs, such as the liver, spleen, or kidneys. Gärtner has demonstrated that when animals with pulmonary tuberculosis are pregnant the fetus is not so very rarely infected with tubercle bacilli. Schmorl and Kockel have met with 3 cases bearing on the subject. (1) Autopsy revealed acute miliary tuberculosis; the subject was in the 8th month of pregnancy, and was brought to the hospital in an unconscious condition. Cesarean section was performed, but the child died after 2 hours. (2) The patient died during pregnancy with acute miliary tuberculosis. (3) A case of chronic laryngeal and pulmonary tuberculosis that died suddenly of profuse hemoptysis. Cesarean section was performed soon after death, but the child was found already dead. In all the cases placental tubercle was found, but only a very little in Case 3, and less in the placenta than in other organs in the other 2 cases. The tubercle bacilli were probably in all 3 cases carried to the placenta in the circulating blood, but in Case 2, in which there was also tuberculous peritonitis, the bacilli, though less likely, might also have been carried from the peritoneum into the uterus by the Fallopian tubes. In cases of acute miliary tuberculosis the bacilli circulating in the blood must be equally distributed to all organs, and the only way to explain why in Cases 1 and 2 less tubercle was found in the placenta than in the other organs is to suppose that the placenta is more resistant than other organs to the bacillus. In all 3 cases tubercle bacilli were found

[1] Intercol. Med. Jour. of Australasia, Mar. 20, 1896.

[2] Beit. z. Path. Anat., xvi., 1895, part 2.

in the fetal placental villi, but only in Case 2 were any bacilli found in the body of the fetus. Even in this case there were no macroscopic changes, but bacilli could be detected in the liver and in a lymph-gland in the neighborhood of the liver. The authors think that the reason why only few bacilli had passed into the fetal circulation is to be found in the changes produced in the vessels of the tuberculous villi. These changes, consisting in the closure of vessels by the formation of hyaline thrombi and the overgrowth of endothelium, to some extent form a barrier hindering the spread of tubercle to the fetal circulation.

The Umbilical Cord.—Interesting cases of tangling and coiling of the cord are reported by L. F. Bishop[1] and Wygodsky.[2] In Bishop's case the death of the fetus was due to an unusual entanglement of the cord. The fetus was born at about full term, but had been dead for some time. The left thigh was flexed on the body, and held in that position by the cord, which passed around it in a "half hitch" in such a manner that each movement of the child had tightened it until its circulation was cut off. The extremity of the child was edematous below a deep sulcus caused by the cord, and the point of pressure on the cord itself was easily seen. [This case is a beautiful proof of the fact that intrauterine amputations are not the result of funic coiling, fetal death resulting long before the severance can be accomplished.] Wygodsky records an instance of excessive coiling of the funis, the cord being wrapped 8 times around the fetus. It was coiled 7 times around the neck and once round the left shoulder, and there was also a distinct knot; it measured over 65 inches in length. The greatest number of coils of the umbilical cord hitherto recorded are—7 (Baudelocque), 8 (Credé), and 9 (Müller and Gray).

Funke[3] of Strassburg records the only assured case in literature of spontaneous intrauterine laceration of the umbilical cord. After the escape of very much amniotic fluid, while the patient on the next day was using the vessel to pass water a long cord fell out of the vagina; it was torn across, but was not bleeding. The fetal heart-sounds had not been audible for 10 hours. The portion of cord hanging out was 25 cm. (10 in.) long. The cervix allowed a finger to pass. Kolpeurysis of the vagina was done for the weak pains and loss of blood. After 12 hours the child was born by the breech; the placenta was removed in pieces $\frac{1}{4}$ hour after. The cord was torn off level with the fetal abdomen, but without opening the belly-cavity; there were no marks of strangulation, but the placenta contained a large blood-clot near the funicular insertion. The cord, 48 cm. long, was easily lacerable; the separation was at the division between the amniotic sheath and the navel-ring, and only a small tag of amnion was left with the fetus. Funke believes the separation was due to multiple twisting and displacement of the cord, for which the hydramnios gave plenty of scope.

The Amnion.—Premature ruptures of the membranes are discussed by Stapleford[4] and Galtier.[5] Stapleford records a case of rupture of the fetal

[1] Am. Jour. Obst., Feb., 1896.

membranes 3 weeks before delivery, with persistence of the gestation to full term, at which time a living child weighing 5 pounds was born. Galtier discusses the cause of primary infection of the amniotic fluid after early rupture of the membranes. The nature of all of the microorganisms has not yet been discovered, but there have been found the streptococcus, staphylococcus, and bacterium coli. The infection produces changes in the consistence, color, and odor of the amniotic liquor, and often causes the formation of gas of fetid odor, even with living children. It may spread with great rapidity after the rupture of the membranes, and may occasion severe secondary and often deadly infections for the mother and child.

The Chorion.—Interesting cases of cystic degeneration of the chorion are recorded by Hastings,[1] Dirmoser,[2] Dorland,[3] and Champneys.[4] In Dirmoser's case there occurred an involvement of the substance of the uterine wall, the patient, however, recovering. Hastings' case was a primipara of 23 years who had been making efforts to terminate her gestation. The patient was over 3 months pregnant, but the uterus corresponded in size to the fifth month of gestation, and the mole filled a pint jam-jar. Champneys reports 2 cases, one a multipara of 40 years, and the other a woman 33 years of age who died of septic infection 9 days after the expulsion of the mole. Dorland reports the case of a multipara 25 years of age, who at the expiration of 4½ months in her fifth pregnancy expelled over 2 quarts of uterine hydatids, after which she made an uneventful recovery. In 1894, Kehrer of Heidelberg reported 50 hitherto unpublished cases of cystic disease of the chorion which he had gathered in 2 years' time from 48 midwives and physicians in the lowlands of Baden, hoping thus to arrive at a more accurate knowledge of the peculiarities of the disease than could be obtained by a study of reported cases. In reply to this paper Dorland has tabulated 100 cases of this rare disease, including 2 hitherto unreported cases, and from a study of this tabulation has arrived at some interesting conclusions. As regards the age of the patients at the time of the molar birth, his figures very closely approximate those of Kehrer. In 8% of his cases and in 4% of Kehrer's the patient was under 20 years of age, the youngest being a single girl of 13; 68% of Dorland's cases and 74% of Kehrer's occurred between the 20th and 40th year, while 16% of Dorland's and 22% of Kehrer's patients were over 40 years of age; 10% of Kehrer's patients were primiparæ, and 24% of Dorland's, while of the 100 cases reported by Dorland, 18%, or 23½% of the multiparæ, had aborted one or more times. The previous condition of health seems to have exerted little, if any, influence upon the development of the chorionic disease. Nausea and vomiting are not especially prominent in the disease, while fully half of the women suffer from anemia and debility to a marked degree; and this is probably due to the hemorrhages from which they suffer. Renal insufficiency, or the kidney of pregnancy, is at least three times as frequent in this condition as in normal gestation, probably the result of the excessive pressure

[1] Canad. Pract., Mar., 1896.

[4] Practitioner, 1896, No. 1.

upon the renal veins. Abdominal pain was a marked symptom in 38% of the cases toward the close of the gestation. It is probable that the origin of this pain is the extreme and rapid development of the uterine tumor which was noted in 85% of the cases. Absence of the uterine souffle is the rule. A number of the women claimed to have felt fetal movements. Uterine hemorrhage is a constant symptom, generally commencing about the second or third month, and at times partaking rather of the nature of a watery or sanguineous discharge than of a true hemorrhage; 63% of the births occurred from the third to the fifth month, inclusive, as compared with 74% in Kehrer's table. 3% of Dorland's cases arrived at term, while Kehrer showed a percentage of 4. In 6% of the cases an embryo or fetus either preceded or followed the discharge of the mass. There is a great tendency to the manifestation of septic intoxication after the delivery of an hydatidiform mole. In 31%, or nearly one-third of the cases, was a certain degree of sepsis recorded; 10% mortality is noted, half of this number perishing from septic infection.

[The relationship existing between cystic disease of the chorion and deciduoma malignum is becoming more clearly defined, and, next to the revival of symphysiotomy, this is the subject that has recently excited most interest in the obstetric world. This newly-recognized neoplasm is a malignant growth from the pregnant or recently pregnant womb. There may have been a recent normal delivery at term or an abortion, or particularly a hydatid mole. The first symptoms are repeated hemorrhage and offensive discharge; then a friable growth can be detected on intrauterine exploration, especially at the placental site; macroscopically the growth resembles placental débris. Anemia, weakness, and cachexia supervene; metastatic deposits occur in other organs, especially in the lungs, and septic symptoms are present. The disease runs a rapid course, and early and complete extirpation of the womb is the only available treatment. The new growth is especially characterized by the presence of certain very large cells, with large nuclei, that bear some resemblance to the large cells of myeloid sarcoma, but that also resemble the so-called "decidual cells" of normal pregnancy.] Papers on the subject have been presented by Bacon,[1] Marchand,[2] Nové-Josserand and Lacroix,[3] Resinelli,[4] Apfelstedt and Aschoff,[5] 2 cases; Champneys,[6] and Fränkel.[7] Bacon's and Champneys' cases resulted fatally without operative interference, as did also Marchand's and Resinelli's. Marchand has collected 15 cases of deciduoma malignum, and no less than 12 of malignant growths following the development of vesicular mole. Eleven died in less than 2 years after the vesicular mole was removed; in 1 there was no after-history beyond the 6th or 7th week, when the uterus contained deposits; in the remaining case the uterus was removed through the vagina, and 3 months later the patient was doing

well. Marchand concludes that malignant deciduoma differs in many ways from carcinoma, although it is of epithelial origin. Fränkel has investigated the changes that take place in the development of this tumor after cystic chorionic disease. He has found that the superficial epithelial layer, or syncytium, of the chorionic villi proliferates considerably when a vesicular mole develops, and it is from this abnormal development of epithelium that the malignant deciduoma is evolved. The deeper cellular investment of the chorionic villus, or Langhan's layer, according to Fränkel, takes no primary part in the development either of the mole or of the deciduoma. Freund[1] reported a case at a recent meeting of the Strassburg Medical Society. The patient, a tertipara, was confined normally in June, 1894. From this time she complained of small hemorrhages occurring daily and gradually becoming more profuse. Examination in June, 1895, revealed a placental polypus, which Freund removed. The growth was about the size of a plum, and had penetrated into the attenuated uterine wall. The polypus under microscopic examination proved to be mainly placental tissue. The bleeding ceased after the operation, but recurred in December of the same year. Examination of the uterus at this time showed a rapid growth of the organ, and at the expiration of 2 weeks it had attained the size of a 4-months' pregnant uterus. In addition, a small secondary tumor was found in the posterior vaginal wall of the nature of a deciduous sarcoma. Vaginal extirpation of the uterus was performed, the woman making a good recovery. Section of the uterus revealed a tumor, villous in character, about the size of an egg, at the site of the removed placental polypus. The villi were not of chorionic structure. Runge,[2] under the title malignant disease of the chorion, describes a malignant tumor of the chorionic villi, the origin of which could be traced to a previous hydatiform mole.

Singultus Fœtalis, or Fetal Hiccough.—Three cases of this curious condition are reported by DeLee[3] and 2 by Hink.[4] Fetal hiccoughs manifest themselves by rhythmic tapping movements in the neighborhood of the fetal shoulders, recurring at irregular intervals. Hink, with the large material of the Vienna Obstetrical Clinic, has diagnosed these movements 7 times in 750 cases, some during pregnancy, others in labor, and can recall 6 other cases of a similar nature. He concludes that there is a variety of singultus without the passage of air through the glottis, and that, therefore, this phenomenon can occur *in utero;* secondly, that the action is unattended with any other noise than the striking of the shoulders against the uterine wall, which produces the jarring and the characteristic short dull tone. No pathologic significance can be attached to the phenomenon. It is not difficult to distinguish this movement from other fetal movements. The position over the back and shoulders and the regular recurrence exclude movements of the extremities and stretching of the back; the frequency, about every 4 seconds, excludes fetal or maternal pulse; while the suddenness of the motion, its jerking character, and the production of a short sound, distinguish it from partial contraction of the uterine

or abdominal muscle. It has been observed as early as the seventh month and up to and during labor.

Vagitus Uterinus.—Flatau[1] has reported a case of a quartipara, at the normal end of an uncomplicated pregnancy, in whom the onset of labor was marked by copious hemorrhage. Placenta prævia lateralis was diagnosticated, and in the hope that the head would descend and act as a tampon, the membranes were ruptured through the partially dilated os uteri. The anticipated result was not realized, and a tampon of iodoform-gauze became necessary. The hemorrhage, however, persisted, and podalic version was performed. With the outer hand grasping the head, an attempt was made with two fingers introduced into the uterus to bring the feet together. In the performance of this act the umbilical cord was compressed, and at once cries were heard. These were repeated when the cord was again compressed. Version was finally effected successfully, and the child at once extracted. The infant was asphyxiated, but was resuscitated by mechanical irritation of the precordium. [The explanation offered for the phenomenon observed is, that air was introduced into the uterus with the hand, and that compression of the cord induced dyspnea, with the resultant cry on the part of the fetus.]

Fetal Traumatism and Death.—An interesting case of intrauterine rupture of the anterior abdominal wall of the fetus, dependent upon some

FIG. 100.—Pygopagus (Jacobi and Tynberg).

unnoticed maternal traumatism, is reported by Brothers.[2] There was associated an absence of genitals and anus, together with an exstrophy of the bladder. The child lived for 25 hours, the napkins showing that urine was secreted.

[1] Centralbl. f. Gynäk., 1896, No. 11, p. 293.

[2] N. Y. Med. Jour., Dec. 7, 1895.

Freiberg[1] reports an intrauterine fracture of the tibia in a child belonging to a family in which other abnormalities in the skeleton had been observed. He remarks that 50% of reported intrauterine fractures are those of the leg, while but a small number are in the region of the lower epiphysis. Westphalen[2] reports 2 cases of fetal death during the last months of pregnancy from direct violence. Vicarella[3] regards the presence of acetone in the urine during pregnancy as a new and valuable sign of fetal death, provided other causes of acetone can be excluded. In an examination of 139 pregnant women he found 9 cases of acetone in the urine. In each of these cases the woman was carrying a dead fetus. In 1 case of hydramnion all the clinical symptoms of a dead fetus were present, but the urine contained no acetone. The woman was subsequently delivered of a living child. [The presence of the acetone is explained by the absorption of partly oxidized albumin from a macerated fetus.]

FIG. 101.—Acephalic omphalosite (Nammack).

Fetal Monstrosities.—In treating of the etiology of monstrosities, Ballantyne[4] gives the following classification of the various theories that have from time to time been advanced: A. Theories of the Past: 1. Supernatural Causes; 2. Physical Causes; 3. Mental Influence. B. Theories of the Present: 1. Mechanical Causes; 2. Diseases of—(*a*) Fetus; (*b*) Fetal Annexa; 3. Embryologic and Germinal States; (*a*) Heredity and Atavism; (*b*) Environment; (*c*) Germ Infection. Remarkable cases of fetal monsters are recorded as follows: Onuf,[5] a case of double formation of the face with cranio-rachischisis involving the whole vertebral column; there were

[5] Med. Rec., Sept. 21, 1895.

present two pharynges, which communicated with each other; an osseous sternum was absent; Kempe,[1] a case of thoracopagous male twins with a common heart, and a transposition of the viscera in one twin; there was one placenta and only one umbilical cord. Playfair mentions 19 such cases as having been recorded; A. Jacobi and S. Tynberg,[2] a case of pygopagus, the fourteenth on record, the children surviving 5 months; the placenta was single, also the cord, which divided into branches 2 inches from its velamentous insertion: an illustration is appended (Fig. 100); Conklin,[3] a pseudencephalic monster, supposed to be the result of a pronounced maternal impression; Nammack,[4] an acephalic omphalosite (Fig. 101), one fetus seeming to have undergone a normal development for 5 months, while the parasite presented a curious instance of malformation and arrested development; a coexisting cyst (hydrencephalocele, springing

FIG. 102.—Fœtus amorphus (Hirst).

from the root of the nose) was also present; the parasite was a shapeless mass, to which was appended one well-formed foot with 7 toes; the other lower extremity was rudimentary; Hirst,[5] a typical case of fœtus amorphus or anideus (Fig. 102), the lowest form of omphalosite, the parasitic fetus being reduced to a shapeless mass of flesh covered with skin; the host in this case was a normal, well-developed child, born alive at full term; Richard H. Wood,[6] Perkins,[7] A. C. Wood,[8] W. A. Wood,[9] and Bowerman,[10] cases of anencephalous monsters; Craig,[11] a case of complete absence of the upper half of the frontal, the entire parietal, and upper half of the occipital bones, together with the hair and scalp; there was also a cleft palate; the child died on the third day of acute

meningitis; W. Reynolds Wilson,[1] a case of congenital malformation due to thickening of the integument (especially of the muscular tissue), complicating spina bifida; Stone,[2] a case of congenital deficiency of the posterior portion of the diaphragm, with the abdominal viscera resting in the thorax; Todd,[3] a case of fetal ectopy of the liver, omentum, and bladder; and Langran,[4] a case of supernumerary fingers. Haven[5] records a case of kynocephalous monster. The mother, Mrs. D———, was since early childhood possessed with a great fear of even the picture of a dog, the result of a so-called maternal impression, the history being that her mother had been frightened by a dog while carrying her daughter *in utero*. Mrs. D———, during the sixth week of pregnancy, had been herself frightened by a dog, and firmly believed that her child would be marked like a dog. Some time later she was jumped upon and bitten by the same dog, and immediately gave birth prematurely to the monster, whose head was precisely similar in shape to that of the dog.

THE PATHOLOGY OF PREGNANCY.

The Pernicious Vomiting of Pregnancy.—Cases of this disease are recorded by Purch,[6] Larat,[7] Lee,[8] Bar and Bienfait,[9] and Charpentier.[10] Purch was compelled to terminate the gestation in his case—a hysteroneurasthenic subject—by the use of the curet at the sixth week, the vomiting ceasing immediately. Gaulard believes that palliatives should be tried until there is a rise of temperature, which he regards as a dangerous symptom; while, on the contrary, Charpentier states that he is now in favor of terminating the pregnancy as early as possible. He does this by introducing into the uterus a short stick of solid silver nitrate, which is left to melt there. [This is an unnecessary and unsafe procedure; the usual antiseptic method of inducing abortion is safe and applicable in every instance.] Disproportion between pulse and temperature is a grave symptom in this disease. Marduel[11] relates an interesting case that resulted fatally 1 month after the induction of abortion. Bar and Bienfait claim good results from faradization of the vagi before or after meals, while Larat has also employed successfully the constant current, the positive pole being placed on the neck over the point of emergence of the right pneumogastric nerve, and the negative pole to the epigastrium. [This method of treatment needs to be tested much more extensively before its real therapeutic value can be determined.] Audebert[12] believes that when it becomes necessary to empty the uterus in the early months of pregnancy because of uncontrollable vomiting, dilatation of the cervix by Hegar's dilators, followed by curettage, is the best and most effective method to employ.

Valvular Cardiac Disease.—This grave and important complication of

pregnancy has attracted the attention of many obstetricians of late. Probably the most exhaustive contribution on the subject is that of Handfield-Jones.[1] He remarks that failure of the ventricle has a distinct effect upon the course of pregnancy. In the early months it leads to abortion, and in the later months to premature delivery. Porak confirms this point, and says that "heart troubles have an evident influence on pregnancy, by provoking metrorrhagias, by determining very often abortions or premature delivery, by producing, it may be, placental lesions, and by acting harmfully on the infant, which sometimes dies before its birth or is born under conditions not favorable to development and disposing toward premature death." The heart during pregnancy and the puerperium is specially liable to undergo fatty degeneration. This may be due to retrograde changes taking place after delivery, or may depend on the premature setting in of these changes, together with an insufficiently oxygenated state of the blood, dependent partly on anemia and partly on lung-disease. The condition of the muscular heart-wall is of more importance during pregnancy than the valvular lesion; many women with valvular lesions pass through their early pregnancies without any sign of heart-failure, but as the heart-muscle becomes deteriorated by the strain of repeated pregnancies they show increasing evidence of cardiac insufficiency. Of all the forms of valvular lesion, mitral stenosis of a marked degree is the most disastrous: this is largely due to the extra strain thrown in these cases on the pulmonary circulation and the right heart. The increased arterial tension, the increased volume of blood, and the increased development of the left ventricle, all tend to produce dilatation of the left auricle and of the right ventricle. The pulmonary circulation is thus kept continually congested, unless pronounced hypertrophy of the right ventricle takes place. At the close of delivery, when more blood collects in the right side of the heart, the risk is increased and the danger reaches its maximum. He further states that, provided a valvular lesion is well compensated and the muscular tissue of the heart can be judged to be sound, and provided also that the patient is a young woman in whom processes of repair may reasonably be expected to go on at a healthy rate, there would be no just reason for forbidding her to marry. If, however, there are any serious symptoms of cardiac disturbance present, or attacks of dyspnea, breathlessness, palpitation on exertion, or hemoptysis, marriage should not be sanctioned. Regarding the action of free bleeding during the third stage of labor, he earnestly bears testimony to its useful effect. A free loss tends to relieve the right heart from undue engorgement and considerably lessens the risk of sudden stoppage of the heart. Equally useful is the application of leeches over the liver or heart during the puerperium when blueness of the lips and face, with dyspnea and pulmonary trouble, indicate an overdistended and failing right ventricle. Of all drugs, strychnin and amyl nitrite are the most useful.

Rosenberg[2] specifies the earliest symptoms of the disturbed heart's action, as dyspnea, palpitation, edema of the face and extremities, and bronchitis, and advises the suspension of every exertion on the part of the patient, the recum-

[1] Lancet, Jan. 18, Jan. 25, Feb. 1, 1896.

[2] N. Y. Med. Jour., Jan. 18, 1896.

bent posture being retained during the greater part of the day. Frequent examination of the urine is indispensable, and a strict milk diet must follow the finding of the first trace of albumin. Cardiac stimulants are necessary. The induction of premature labor is often not followed by relief, the woman's condition being one of extreme peril from asystolism. Success can only be expected if the pregnancy be terminated before the onset of serious symptoms. During labor the patient should be placed in the half-sitting posture, and alcoholic stimulants, camphor, strychnin, and strophanthus given; the nitrites are indicated whenever the pulmonary circulation becomes embarrassed. The main indication is to deliver as soon as possible. During the puerperium rest, simple diet, and appropriate stimulants form the rational basis of treatment. Hirst,[1] in addition to the heart-tonics already mentioned, gives his patients iron in full doses. During labor he deeply incises the cervix on all four sides to facilitate forceps-delivery and to favor loss of blood. As soon as practicable a large pad above the umbilicus and a tight binder should be applied to compensate for the sudden diminution of intraabdominal pressure. Phillips[2] states that these patients are especially liable to septic infection. Dorland has met with a case, hitherto unreported, of a young woman, 24 years of age, in the eighth month of pregnancy, with marked symptoms of cardiac failure the result of a mitral stenosis. There were intense dyspnea, hemoptysis, palpitation, and strong pulsation of the cervical vessels. During his absence from the city the patient fell into labor, was delivered of a living child, but died suddenly 9 hours later. Phillips[3] reports 4 cases—1 of aortic stenosis, 2 of mitral disease, and 1 of chronic mitral disease—in which labor was followed by acute endocarditis with regurgitation and death; Macé,[4] 2 fatal cases; and Wessinger,[5] 2 cases terminating fatally.

Pregnancy and Exophthalmic Goiter.—Signier[6] reports a case in which exophthalmic goiter began with a pregnancy, the symptoms ameliorating after delivery. He believes that the pregnancy was really the cause of the enlargement of the thyroid gland. Possibly the diminution in its size after parturition depended on some temporary condition in connection with the puerperium. Even so simple a cause as the necessary rest may explain the favorable change, which, after all, may not prove permanent.

Albuminuria and Nephritis in Pregnancy.—Gossmann[7] denies that the albuminuria of pregnancy always ends in the chronic form. He refers to the case of one patient who had acute nephritis during 8 pregnancies, and yet was always free from kidney-symptoms when not pregnant. He induced labor without difficulty by means of vaginal douches, and used this means alone in 2 cases. Grimsdale[8] records a case of albuminuria and general anasarca of the mother during pregnancy, associated with general edema of the fetus and fluid distention of the fetal abdomen and hypertrophy of the placenta. In

this instance Grimsdale believed that the disease was primarily fetal, the course of events being disease of the fetal liver and kidneys, causing general dropsy and ascites of the fetus and hydramnios, and secondary to these appeared the maternal nephritis. Brinton[1] makes the astonishing statement that "experience and statistics prove that women who have chronic nephritis conceive and carry their children to full terms without having convulsions. Indeed, it seems that if they do not abort they are less liable to eclampsia than women who for the first time develop kidney-disease during pregnancy." [In strong contradistinction to the foregoing we have the positive statement of such an authority as Tyson that unless the pregnancy be prematurely terminated it will inevitably result fatally. Such has been his experience, and such has been the experience of other men of equal standing. We strongly urge the extreme gravity of the condition, and moreover would add that women suffering from chronic nephritis develop grave manifestations at least 2 or 3 months earlier in gestation than those women in whom the renal inadequacy develops during the course of the gestation.]

Pregnancy and Diabetes.—Partridge[2] contributes a paper based on a study of 25 cases of this disease complicating the pregnant state. About one-half of these acquired diabetes during pregnancy, the other half already having the disease before pregnancy occurred. In the former class recovery took place in about three-fourths, with, however, an exhibition of a tendency to recurrence in a subsequent pregnancy. In the class in which pregnancy occurred in women already subjects of diabetes safety through delivery and the lying-in period was apparent in about two-thirds of the cases. Death of the fetus is noticed in about one-half of the cases. Premature delivery is observed in a large proportion of the reported cases, due to the presence of the dead fetus rather than to the direct influence of diabetes. There were 6 deaths in coma or collapse during or near the time of labor—1 in a woman who had diabetes before gestation, while 5 were in patients who acquired the disease during pregnancy. As to treatment by the artificial interruption of pregnancy, Partridge concludes that each case must be considered by itself. In a case of long history, with attacks of threatened coma or collapse, the indication for abortion seems plain. In the absence of these critical symptoms by dietetic and other treatment we rarely fail to obtain some improvement, and more radical measures are unnecessary.

Mental Disease in Pregnancy.—In writing upon puerperal insanity Dagonet[3] states that the puerperal condition, properly speaking, refers only to the functional and organic modifications that take place in women during and after parturition, before the return of the menses or the physiologic establishment of lactation. But from the point of view of puerperal insanity this period may be divided into three periods: (1) gestation; (2) puerperal conditions proper; (3) lactation. The following statistics show the relative frequency of psychosis in each of these periods: gestation, 3.1 in 100; puerperal condition proper, 9.2 in

[1] New Orl. M. and S. Jour. Jan., 1896.
[2] Med. Rec., July, 27, 1895.
[3] Progrès méd., Apr. 7, 1894.

100; lactation, 3.6 in 100. According to Macé, insanity caused by pregnancy generally develops about the end of the fourth month, and increases progressively. Melancholia is the most frequent form. Schmidt gives the following proportions: 52.9 in 100, melancholia; 31.3 in 100, mania; 10.3 in 100, systematized delirium; 5.8 in 100, general paralytic dementia. Macé observes that labor seldom relieves this form of mental disease; on the contrary, the symptoms are generally aggravated, and melancholia often assumes the form of more or less violent mania. Abortion, sometimes recommended as a curative measure, should be strictly forbidden. Gestation, with these patients, is usually normal, and abortion seldom occurs spontaneously. The opinion advanced by some authors that pregnancy exerts a beneficial influence upon insanity already established is not sustained by statistics. Esquirol believes that marriage and labor generally stimulate the disease. When the psychosis appears at an early period the prognosis is more favorable than when it occurs toward the end of gestation, but it generally persists for several months, and relapses may be expected in subsequent pregnancies. The causes of puerperal insanity proper —that is, insanity that develops during the period following labor before the the organs of generation have resumed their normal functions—are divided by Campbell-Clark into predisposing causes and producing causes. In the first category hereditary predisposition is the most important, as it exists in 56% of these cases. The complicated influences affecting a first pregnancy are next in order. Nearly half the patients suffering from this form of psychosis are primiparæ. Among producing causes infection occupies the first rank—infection of the uterus or of other organs. Campbell-Clark reports 70 of 100 cases caused by infection—66 by infection of the uterus, 4 of the kidneys. More than half these patients were under the influence of intense moral emotions; and we realize the importance of this influence when we consider the large number of women who suffer from puerperal infection. Dr. Idanof gives the proportions as 8 or 9%, and the comparative variety of puerperal insanity. The disease usually appears about the fourth or fifth day. Irritability, insomnia, headache, agitation, diminished secretion of milk, are premonitory symptoms. Fever may or may not be present, but the head is always hot. Sometimes the disease assumes a fatal form, when the tongue becomes dry and furred, the secretions cease abruptly, and the patient falls into a comatose state, which soon ends in death. Puerperal insanity proper assumes the most diverse forms: mania in 48.7%; melancholia in 37.9%; systematized delirium in 5.8%; acute dementia in 5.5%. The prognosis is favorable in most cases, more favorable in mania than in melancholia. Patients suffering from insanity after prolonged lactation usually present symptoms of extreme exhaustion. The prognosis here is not unfavorable, but more grave than in puerperal insanity proper. The therapeutic indications are the same in all kinds of puerperal insanity. Treatment consists in the removal of all exciting causes, a tonic régimen, mild purgatives, injections of chloral hydrate, and other soothing influences. Valenta[1] reports the case of a primigravida of bad hereditary history who became

[1] Arch. f. Gynäk., Bd. xlix. H. 1, 1895.

excessively hysterical when she discovered that she was in a pregnant condition; her paroxysms resembled those called clownish hysteria. She became so weakened and emaciated by the disorder that it was necessary to empty the uterus. As soon as the membranes were ruptured and the amniotic liquid escaped there was a marked improvement in the patient's condition. Barbour[1] records the case of a single primigravida, aged 20, who was well during pregnancy until fetal movements developed; she was then seized with attacks of hysteric paralysis that produced a condition closely resembling dementia. Muscular contractures with areas of anesthesia developed. Labor came on spontaneously, with epileptiform spasms with each pain, fever, and rapid pulse. The fetus died during the labor, and, the mother's pulse failing, delivery was completed by forceps. From the moment when the membranes ruptured the temperature declined, becoming normal; the paralysis disappeared, but the impairment of sensation and contractures remained. Temporary improvement followed the labor, with return of sleep and appetite. The patient, however, again failed, and died with high temperature. Postmortem examination showed thickening of the membranes of the brain, with softening on the right side, involving the internal capsule and extending to the base. The body of the fetus showed the same contractures that the mother exhibited, including a peculiar attitude of the right arm and hand. This was not due to rigor mortis, but was proved by dissection to be due to muscular contraction.

Pregnancy and Infectious Diseases.—Van der Willigen[2] in closely observing 432 cases of small-pox in women under 50 years, made particular note of 80 who were pregnant. Of these 15% died, while the mortality of the nonpregnant cases was 11.08%. Van der Willigen, like some previous authorities, finds that pregnancy increases the predisposition of a patient to the graver forms of variola. In the 80 cases confluent small-pox was seen in 4 and the hemorrhagic form in 6 cases; all the 10 died. In the 352 nonpregnant cases the confluent form was observed in 3 and the hemorrhagic in 11 patients; 2 of the confluent cases recovered. Two pregnant women died of milder forms; of the total, 12, there died 5 undelivered, the most of the others very shortly after birth without any trace of puerperal infection. Of the primiparæ, 9% died, of the multiparæ, 17.25%; 6.25% of women attacked by small-pox early in pregnancy died, whilst the mortality of those who were infected later amounted to 20.83%. Abortion or premature delivery was noted in 23 of the 80 cases during the course of the attack of small-pox. In 6 the same took place after convalescence from the disease; 16 children were delivered alive in cases in which the small-pox was still in progress, 8 at term, and 8 prematurely; only 3 lived longer than 6 months. Several died of variola; 2 were clearly born with it.

Pregnancy and Tuberculosis.—Maragliano[3] asks the important question, Should pregnancy in tuberculous women be permitted to go to term? as a result of the following personal observations: In 835 phthisical patients the

[1] Edinb. Med. Jour., June, 1895. [2] Nederl. tijdschr. v. Geneesk., No. 11, 1895.
[3] Centralbl. f. Gynäk., No. 29, 1895.

onset of the pulmonary trouble dated from pregnancy or childbed in 226 cases. Similar observations in the cases of pregnant and nonpregnant phthisical women, conducted over an equal period of time (21 months), showed that among the former death occurred in 94%, and among the latter in 18%. In 42 pregnant women with circumscribed tuberculosis, only 3 cases remained stationary, while in 7 cases death occurred within 3 months after childbirth, in 9 cases within 3 to 6 months, in 10 cases between 6 and 9 months, and in 4 cases after the period of 1 year; finally, 9 women died in childbed.

Sepsis and Pregnancy.—Sepsis occurring during pregnancy is exceedingly rare. However, Bar and Renon[1] presented at the recent Congress at Bordeaux a clinical report of a case of *streptococcism* in pregnancy. A woman was admitted into the hospital suffering from high fever and about 8 months pregnant. She experienced occasional pains. Before any obstetric manipulations were performed some cervical secretion was removed for examination. Cultivations proved that the secretion contained the streptococcus. The labor was hastened on account of the illness of the patient. Specimens of the maternal placental blood were cultivated and colonies of pure streptococci were obtained. The child died before birth. Samples of its blood from the placenta, liver, and heart and fragments of the liver and lungs were cultivated. The cultures remained sterile. The mother died 53 hours after delivery, and pus was found in the parametrium. Bar and Renon maintain that the streptococcism provoked labor. Though the fetus succumbed, there is no evidence that the germs invaded the fetal organism through the placenta.

Gonorrhea and Pregnancy.—The clinical importance of gonorrhea during pregnancy, labor, and the puerperal state is the subject of a contribution by Fehling.[2] He has seldom found it necessary to treat urethritis occurring from this cause. The patient is directed to drink an abundance of water, and occasionally sodium salicylate or salol is given. In obstinate cases iodoform-bougies are placed within the urethra. When vulvitis and vaginitis are present, antiseptic injections produce good results. Normal saline solution and potassium permanganate are useful in the form of douches. Twice weekly Fehling is accustomed to pencil the mucosa with a 5 to 10% solution of silver nitrate, using iodoform as a powder. Absorbent cotton should be placed between the labia, or compresses wet in lead-water. When erosions are present upon the cervix, silver nitrate may be used with a camel's-hair pencil. Gonorrheal salpingitis is treated in the usual manner, by rest, counter-irritants, and morphin. Scarification of the neck of the uterus is sometimes practised when the pain is excessive. [The danger of the induction of abortion must be borne in mind, however.] Should it be necessary to induce labor in a patient having gonorrhea, it is well to douche the vagina with normal saline solution, or with an antiseptic if the infection be in an acute stage. In cases in which there have been erosion and catarrh of the cervix for a long time the tissues are rigid and dilatation is slow; douches are of value, and multiple incisions are

[1] Répertoire univers. de Obstét. et de Gynéc., Sept. 25, 1895.

[2] Münch. med. Woch., Dec. 3, 1895, No. 49.

often required in these cases. No alteration in the placenta has been observed in gonorrheal patients.

Uterine Displacements in Pregnancy.—Forbes and Reid[1] record a case of retention of from 60 to 70 ounces of urine from a retroverted gravid uterus, the vesical tumor simulating an ovarian cyst, while Burrage[2] records 8 cases of retrodeviation of the pregnant uterus, including a case of pregnancy in an incarcerated cornu and a case complicated by an ovarian tumor. A complete prolapse of a pregnant uterus at the fifth or sixth week is reported by Hundley.[3] The condition not being recognized, a sound was introduced into the uterine cavity and the cervix amputated at its vaginal attachment; the woman aborted the same evening. [It is quite possible to make a positive diagnosis of pregnancy at the sixth week with the uterus in its normal position, and, no doubt, had pregnancy been suspected in the present case some of its manifestations could have been readily discovered.]

Metritis and Endometritis.—Emmanuel and Wittkowski,[4] investigating 3 cases of endometritis during pregnancy, found numerous intracellular diplococci closely resembling gonococci in the true decidua in the first, and in the serotina in the second. These microorganisms did not stain by Gram's method. The subject of the first observation again suffered during a subsequent pregnancy from endometritis, probably contracted before conception, and aborted at the fourth month. The true decidua were greatly altered and thickened, and were strewn with small round cells, particularly abundant on the surface. In these cellular foci Emmanuel found long filaments made up of short bacilli, staining by Gram and Weigert's method and growing in agar-agar. This bacillus had many of the characteristics of the bacillus coli communis, but differed in its reaction to Gram's method. From these studies they conclude that this condition results from a previous chronic endometritis that becomes acute upon the supervention of pregnancy. Veit agrees with this conclusion, and calls attention to cases of myxoma of the chorion in which the decidua contains microorganisms. He does not believe, however, that the ovum is infected and infects the mother; but, on the contrary, that myxoma of the chorion is usually caused by endometritis that has existed prior to conception.

Cumston[5] does not regard parenchymatous metritis as so important a factor in the etiology of abortion as is endometritis. That form, however, arising from puerperal infection is very prone to induce an abortion should the woman conceive. Syphilitic metritis, also, is a not uncommon cause of abortion. Infectious metritis is a most virulent form of the disease, almost invariably resulting in death of the ovum and its ultimate discharge, and not infrequently in maternal death also. Should abortion be threatened under these circumstances, it should be facilitated in order to remove as much of the diseased material as possible.

Pregnancy complicated by Pelvic Suppuration.—Michie [1] records a series of interesting cases in which pus had formed during pregnancy within the pelvis. The first case was that of a middle-aged married woman, who was 4 months pregnant when she developed appendicitis, and was operated upon, a perforated appendix being removed, together with a concretion lying at the bottom of an abscess within the pelvis; the cavity was drained by an India-rubber tube; the patient recovered in 3 weeks, and went to term and bore a living child in spontaneous labor. The second was the case of a multipara who was seized several times before labor with peritonitis, which was worse after delivery; the abdomen was opened, and several pints of offensive pus were removed; the Fallopian tubes contained pus and the ovaries were soft, gangrenous, and almost black; the abdomen was flushed with warm water and drained by a glass tube; the patient recovered. The third was the case of a primipara 6 months pregnant, who fell off a chair, causing pain and tenderness in the abdomen; she miscarried 6 days later, and was attacked by peritonitis; abdominal section was performed and several pints of pus evacuated; the abdomen was drained with a glass tube, and the ovaries and tubes allowed to remain; the patient recovered and subsequently became pregnant. He then records the case of a young woman 4 months pregnant in whom the uterus was retroverted, while both tubes and ovaries were diseased; they were removed by abdominal section, the patient making a good recovery. He also reports a fatal case in a multipara aged 40 years, about 5 months pregnant; she had been kicked and abused by a drunken husband; on examination, peritonitis was present and pregnancy was observed; at operation the pelvis contained a half-pint of seropurulent fluid, with double pyosalpinx. The abdomen was flushed with warm water and a rubber drainage-tube inserted; on the third day miscarriage occurred, followed by death on the sixth day from septic peritonitis. Finally, he reports an interesting case of a multigravida who was 3 months pregnant. On examination an ovarian cyst was diagnosticated complicating the pregnancy; labor-pains came on, with fever and high pulse; delivery was impossible, as the pelvis was blocked by the tumor; accordingly, the abdomen was opened, and an adherent ovarian cyst containing fetid pus was removed from the right side. No drainage was employed. Shortly after the operation the patient's abdomen became distended, and it was necessary to insert a glass drainage-tube; improvement followed and the tube was removed, but had to be reinserted; the patient made a good recovery. She afterward presented herself for treatment, suffering from retroversion of the uterus; there was also found an enlarged and cystic ovary, which was removed by abdominal section. Upon reopening the abdomen, the adhesions which had been found at the first operation had entirely disappeared.

Pregnancy in a Double Uterus.—Interesting cases are recorded as follows: Wendling,[2] a case of double uterus, with repeated hemorrhages from one uterus and pregnancy in the other, the patient being 20 years of age and single. The upper part of the vagina was divided by a thin septum, with a

[1] Prov. Med. Jour., July 1, 1895.

[2] Wien. klin. Woch., No. 2, 1896.

cervix on either side; Eustache,[1] the case of a woman pregnant for the second time and affected with leukorrhea since her first confinement. An examination revealed a double os, one closed and the other dilated, with a flow of mucopus from the latter. The left uterus was pregnant, and pregnancy advanced to term. Three days after the labor the patient experienced pain in the right half of the abdomen, and expelled a triangular membrane 4 cm. in diameter, this being evidently the caduca formed in the right uterine cavity. Three successive pregnancies have since occurred alternately in the right and left segments; each labor was followed on the third or fourth day by the expulsion of membranes from the nongestating cavity; Matveïff,[2] the case of a primipara confined at the beginning of the ninth month; a small fetus (weighing 1500 grams) was expelled from the right side of a double uterus; and Goulligod,[3] a case of abortion in a bifid uterus the seat of a double pregnancy; the right side aborted, and several hours later a fetus of $3\frac{1}{2}$ months was expelled from the left side. Ameiss[4] records a case of uterus didelphys and vagina duplex in a woman of 24 years who had been married 5 weeks. Her menstrual history had always been regular since puberty at 15, but coitus was rendered impossible by the vaginal septum—a membranomuscular band which stretched across the middle of the vaginal orifice in an anteroposterior direction, dividing the introitus into two orifices. The left vagina, $7\frac{1}{2}$ cm. long, was wider than the right, although much below the normal in size; the right vagina was 9 cm. long; the two uteri were distinct, each being movable separately and being in a latero-retroverted position. The left ovary was of about normal size, but rather close to the uterus; the right ovary was but a small, thickened nodule adherent to the uterus. The vaginal septum was removed by operation, and 3 months later the woman became pregnant in the left uterus. Pfannenstiel of Breslau, in a paper read before the German Gynecological Society at Vienna in 1894, tabulated 18 cases of pregnancy in uterus didelphys, 12 of which were delivered at full term, some a number of times; in most of these cases no trouble occurred during labor. The menstrual history in these cases is of interest. In a case recorded by Sprigg[5] examination showed that the flow emanated one month from one uterus and the next month from the other. Uterus didelphys is not as rare an occurrence as was formerly believed. In discussing Ameiss's paper, Tuholske reported the fourteenth case on record of pregnancy at full term in a uterus of this description. Being called in as a consultant, he was informed that a foot was presenting, but on making an examination found a tightly closed os. Repeated examination, however, showed a double vagina and uterus didelphys, with a breech-presentation in one organ. The labor was tedious and the child was stillborn, but the woman made a good recovery. Subsequently the vaginal septum was removed, and the woman again conceived, passing through a normal pregnancy and labor.

Spontaneous Rupture of the Uterus.—Instances of this rare accident

[1] Jour. des Sci. méd. de Lille, No. 40, 1895.
[2] Gaz. des Hôp., July 6, 1895.
[3] Univ. Med. Jour., Aug., 1895.
[4] Am. Jour. Obst., May, 1896.
[5] Ibid., July, 1895.

are recorded by Reynolds,[1] Doléris,[2] Chéron,[3] two cases, Marks,[4] and Townsend.[5] All the cases terminated fatally. In Marks' case gestation had advanced to the eighth month, and 2 perforations were found in the uterine wall near the fundus, while several nonperforating ulcerations were detected elsewhere. Townsend's case occurred during a normal labor without obstruction (save that due to the size of the child—13 pounds) in an enormously fat woman. There was a large transverse tear in the lower uterine segment involving the vagina and a portion of the bladder. Reynolds' patient was a stout alcoholic, weighing 240 pounds. The rent in this case involved the entire left side of the uterus from the cervix to the fundus. Doléris' patient was a woman 32 years of age, an alcoholic, who was markedly cachectic and in a quasi-scorbutic condition. Profuse hemorrhage occurred during labor, and, the condition of the child becoming alarming, version and extraction were performed, the child being delivered stillborn. The mother died several days postpartum without symptoms of peritonitis, and a postmortem examination revealed an extensive rupture of the lower uterine segment. A most remarkable feature of the case was the entire absence of shock. [In all of these cases the predisposing cause of the rupture was a fatty degeneration of the muscular fibers of the uterine wall, and it is probable that this is the cause of the accident in all instances not secondary to some abdominal operation.]

Traumatisms and Operations during Pregnancy.—An exceedingly interesting, and perhaps unique, case of bullet-wound of the pregnant uterus is recorded by Pritchard.[6] The patient was 7 months advanced in pregnancy, and had been shot with a revolver in the abdomen. She was admitted to the Bristol Infirmary 2½ hours afterward in a condition of collapse. The bullet entered 3 in. above and 2 in. in front of the right anterior superior spine (see Fig. 103). There was little hemorrhage and no great distention of the abdomen. The fetal heart was easily heard. A probe would not pass through the abdominal wall. There was no distinct evidence that the bullet had penetrated the abdomen. Later in the evening the bullet was found ½ in. above and 5 in. behind the left anterior superior spine, and was extracted under cocain. As

the patient's pulse was increasing in quickness and the distention of the abdomen was greater, abdominal section was performed. The uterus was found to have been shot through, and accordingly was opened, and a dead fetus and placenta, both perforated by the bullet, were removed. The uterus was amputated, and the pedicle fixed outside the abdomen at the lower end of the wound. Three coils of small intestine had been perforated; these were closed with silk suture. An artery in the mesentery had been severed and required ligature. The peritoneal cavity was emptied of blood and clots, and thoroughly washed out with boric solution. Drainage with gauze and a glass tube was employed. The patient survived 6 days and 12 hours. She had bowel-movements, and a sanguineous fluid, which became purulent, was removed from the drainage-tube. At the autopsy death was found to have resulted from purulent peritonitis in three or four foci, the worst being inside the wound of exit. The intestines were completely sealed. The pedicle was also in good condition. The peritoneum had evidently become infected by the bullet after passing through the intestine. Examination of the body of the fetus showed that the shot passed through the pleura, diaphragm, and liver.

The Indian Med. Record, May 16, 1896, quotes the following case: "A remarkable case has recently been published in an Italian contemporary of a woman who, when 6 months pregnant, was stabbed twice in the abdomen. Both wounds penetrated the abdominal cavity, and, as there were signs of internal hemorrhage, the abdomen was immediately opened. The uterus was found to have been perforated in two places by the knife, and the wounds were closed by sutures, the hemorrhage being thus checked and the immediate danger removed. The patient progressed very well until the third day, when severe pains came on, and on the next day an abortion took place from which she completely recovered. The fetus was dead, and on being examined it was found that one stab had penetrated into the left side of its chest, and that another had wounded the small intestine in 2 places, purulent peritonitis having thus been set up. The case, we believe, is unique, and the fact that peritonitis from the intestinal wound had been caused in a 6 months' fetus is a clinical fact of the greatest interest."

Operations during Pregnancy.—A number of operations have been performed during the year for ovarian and uterine tumors complicating pregnancy. Hirst[1] records a rare case of dermoid cyst in pregnancy. In 2275 ovariotomies in general collected by Olshausen only 80 were for dermoid cysts —3.5%. In Dsirne's complete statistics of 135 operations for ovarian tumors in pregnancy there were 10 for dermoid cysts. Homans has since reported an operation, and Hirst's is the twelfth case on record. The tumor closely resembled an extrauterine pregnancy. Rubeska[2] reports the thirteenth case operated upon successfully; Staude,[3] the fourteenth; Delagénière (see below), the fifteenth; and Denny,[4] the sixteenth. Jetter has found that 19% of ovarian

[1] Am. Jour. Obst., Aug., 1895. [2] Monatsh. f. Geburtsh. u. Gynäk., 1895, Bd. ii. H. 3.
[3] Ibid., Bd. ii. H. 4, 1895. [4] Boston M. and S. Jour., May 7, 1896.

tumors discovered during pregnancy are dermoids, while in other series of ovarian tumors found in those not pregnant but 4% are dermoids. Rosenfeld[1] records a 4 months' pregnancy complicated by a large vesical calculus in a woman 27 years of age. The calculus prevented the escape of urine, and operation was imperative. Abortion occurred 40 hours after the operation. The patient perished of pneumonia and heart-failure a few days after the performance of the operation.

Operations for ovarian cyst in pregnancy are recorded as follows: Merkel,[2] a successful bilateral ovariectomy; Mainzer,[3] the same; Breed,[4] a case of pregnancy complicated by ovarian cyst, but not operated upon until after delivery; Delagénière,[5] 3 successful cases, 1 a dermoid; Rubeska,[6] 2 successful cases; and Staude,[7] several cases, in 1 of which he was compelled to perform ovariotomy through the vagina during the actual progress of labor, probably the only case of the kind on record. [The general consensus of opinion is that ovarian tumors in pregnancy should be removed as soon as discovered; this does not necessarily mean the loss of the product of conception.]

Operations for fibromyomata and other uterine tumors complicating pregnancy are recorded by Elder,[8] Bernardy,[9] Cameron,[10] Leopold,[11] Fehling,[12] Hardon,[13] Frank,[14] Kelley (J. T.),[15] 2 cases, and Murphy.[16] Bernardy's and Fehling's cases were operated upon for carcinoma, the former at $4\frac{1}{2}$ months and the latter at 7 months. Bernardy's case perished on the fourth day of heart-failure: the other cases all recovered. Frank's case is remarkable in that the tumor delivered itself spontaneously through an incision in the abdominal wall 3 weeks after the incision had been made. Rosenberg[17] records 4 cases of pregnancy complicated by fibroid tumors of the uterus varying in size from an orange to a fetal head. Operation was not required, each case being successfully delivered and passing through a normal puerperium. The tumors decreased rapidly after delivery in each case, and Rosenberg contends, in view of this experience, that myomectomy should never be performed during pregnancy unless some exigency arises. In speaking of fibroid tumor complicating pregnancy, Kelley[18] states that if the growth be situated above the cervix, two operations stand paramount—myomectomy and hysterectomy. Leopold[19] lauds the former and quotes statistics; he gives by this operation for the 10 years from 1884 to 1894 a maternal mortality of 17.4%, and 37.13% for the children. Rosenberg follows Leopold with a paper giving in detail 4 cases of noninterference that terminated favorably, and seems to think operation seldom necessary; but 2 of his cases were not recognized until after labor, and in the 2 others, 1 at

[19] Loc. cit.

full term was only the size of an orange, and the other at 2 months was scarcely to be recognized. In Lafour's[1] statistics of 300 delivered by the natural passage there is a maternal mortality of 25–55%, and for the children 77%. Stavely[2] has collected 33 cases of myomectomy that show a maternal mortality of 8 deaths, or 24.25%; and, since 1889, 17 cases have been reported, with a mortality of 11.75%, showing that with improved methods of operating the operation is becoming less dangerous. This method can be employed when the tumor has a comparatively small base and is not adherent. Kelley reports 2 cases, 1 delivered at term with forceps, the patient almost perishing from postpartum hemorrhage due to a closely adherent placenta which was situated just over the site of the tumor, and the other having a hysterectomy performed at 2 months with a successful result. Crowell[3] (H. C.) reports a case of $3\frac{1}{2}$ months' pregnancy complicated by a large fibroid successfully treated by hysterectomy, and a similar case is recorded by Ruth,[4] the patient perishing after the operation, her condition having been bad before its performance. In such a case he advises ligation of as much of the blood-supply as can be safely done without causing sloughing, and then closing the abdomen quickly; abortion should be produced later, and a final hysterectomy still later, if it seems indicated.

Missed Abortion.—Orloff[5] and König[6] report cases of so-called missed abortion. Orloff's patient had borne 10 children, and came to the clinic with a history of icterus and vomiting of blood. There was also enlargement of the abdomen, and puncture was made to relieve the pressure-symptoms. A diagnosis was made of cirrhosis of the liver, with intestinal hemorrhage. The patient shortly afterward died, and upon postmortem examination an impregnated ovum was found lying in the right horn of the uterus. The ovum had ruptured, and only the chorial sac remained. So far as the history and appearance of the tissues indicated, the ovum had remained for more than a year within the uterus. König's case was a woman 37 years of age, who advanced normally in the fifth pregnancy until the third month, at the expiration of which time the symptoms of gestation suddenly ceased, and the patient began to suffer from chilly sensations and from a feeling as if she were carrying a heavy weight in the abdomen. In addition she suffered from labor-like pains. Fourteen months later she expelled from the uterus an ovoid body 8 cm. long, which on close examination proved to be a fetus surrounded by amnion and blood-coagula. The menses then recurred regularly, and the woman regained her normal health.

Missed Labor.—[Prolongation of pregnancy is not an uncommon occurrence, but the two following cases are of exceptional interest.] Resnikow[7] records a multipara who had borne twins. While pregnant at a subsequent time she had a severe fever which lasted 2 months; during the first day of the

disease she had labor-pains, but nothing came from the womb. Some time after this there began to be a discharge of pus from the vagina, and a year afterward with the pus bits of bone escaped. This persisted at intervals for 4 years, and the patient became very much emaciated. She had occasional attacks of high fever, and lost flesh and strength to a very marked degree. Menstruation did not return during the 4 years. Upon examination no evidence of inflammation about the pelvis was found; it was evident, however, that pieces of bone were contained within the uterine cavity. After suitable preparation the uterus was dilated with Hegar's dilators, iodoform-gauze tampons, and laminaria tents. Sufficient dilatation was secured to permit the extraction of the skeleton of a fetus of 7 months. The uterus was thoroughly disinfected, and the patient made a good recovery. It is supposed that during pregnancy the patient suffered from typhoid infection, which caused the death of the fetus and led to its subsequent suppuration. [This is a case of more than ordinary interest, embracing not only the prolongation of pregnancy far beyond term, but also showing the possibility of fetal infection from the mother.] Kahn[1] records a very interesting case of an octipara, 30 years of age, who was admitted to the hospital in Nov., 1894. Her menstrual history had always been normal, the last menses having occurred 11 months before. She believed herself to be pregnant, and stated that 5 months after her last period she had felt life for more than a month. At that time she contracted a severe cold, which developed into a peritonitis that persisted for some weeks. After this attack she ceased to feel life. During the 5 weeks prior to her entrance into the hospital she complained of a stinking vaginal discharge which contained shreds of tissue, but no bones. Her general condition on admission was very poor. Her pulse was rapid and her temperature ranged between normal and 102° F.; the urine was albuminous. In the abdomen palpation revealed a painful tumor that extended for 2 fingers' breadth above the umbilicus. The cervix was situated high up and was hard to the touch; the os admitted 1 finger. The intrauterine sound encountered a hard mass. After thorough disinfection of the vaginal canal, a strip of iodoform-gauze was introduced into the cervix, and this procedure was repeated daily for 5 days. The patient was then etherized, the cervix dilated manually, and an entire fetal skeleton (5 months old) was removed from the uterine cavity; the soft structure of the fetus and the placenta had entirely disappeared. Intrauterine irrigation was made with lysol and the cavity tamponed with iodoform-gauze. Although the uterus rapidly decreased in size, the general condition of the patient did not improve, and she died 3 weeks later of septic infection. [The usual history of these rare and interesting cases is about as in the foregoing instance. So long as the atmospheric germs do not gain entrance to the uterine cavity, the woman does not experience any inconvenience other than that incumbent upon the presence of an abdominal tumor. When the germs ultimately find entrance to the amniotic sac, a rapid disintegration of the tissues occurs, and the woman is subjected to all of the risks of septic intoxication.] F. A. Stahl[2]

[1] St. Petersburg. med. Woch., No. 2, 1896.

[2] N. Am. Pract., Aug., 1895.

reports a case in which he induced labor 302 days after the last menstrual period. When at term, labor-pains had set in, and for 3 hours were strong and regular; they then gradually died away. At the time of delivery the perineum was badly torn, owing to the great size of the fetal head. Ossification of the cranial bones had advanced very far, and made the parts incompressible. The fetus weighed 12 lb. 8 oz., the placenta and membranes 2 lb. The measurements of the head were: occipitofrontal diameter, 15 cm.; biparietal, 13½ cm.; bitemporal, 12 cm.; occipitofrontal circumference, 41 cm. The mother made a good recovery. [That a head of such dimensions could be delivered at all without primary perforation is a noteworthy point.]

Accidental Hemorrhage.—Cases of premature detachment of the placenta are reported by O'Gorman [1] and Blackwood.[2] Both fetuses perished, but the mothers recovered. O'Gorman's case was in the seventh month of gestation, and Blackwood's case in the ninth month. [Nothing is stated in either case as to the probable cause of the separation, whether due to fatty degeneration of the tissues or to traumatism.]

Placenta Prævia.—Interesting cases are recorded as follows: Long,[3] a multipara in the seventh month of the tenth pregnancy, in whom, after removal of the placenta centrally situated, an acute inversion of the uterus was discovered; this was replaced manually, and an uneventful recovery followed; Brindeau,[4] a case of spontaneous delivery of a living child through a centrally implanted placenta. The woman was in the seventh month of her fourth pregnancy, and no bleeding occurred during the delivery; some moments later, however, a free hemorrhage occurred, and the placenta was then found attached to the lower uterine segment close to the cervical opening all around; on removing it there was found an opening 6 inches in diameter in the center of the placental tissue, through which the child had escaped; Bayliss,[5] a case of partial placenta prævia; Stanton,[6] 1 case of partial and 2 of central implantation; Shaw,[7] 2 cases of central implantation treated by Champetier de Ribes' bag, both fetuses perishing; Noer,[8] 4 cases, the child surviving in 1 instance; Cree,[9] 2 cases of partial and 1 of complete placenta prævia, the child being dead in the last case; Nijhoff,[10] 1 case of central implantation, the child surviving; and Boss,[11] 133 cases that occurred between April, 1884, and April, 1894, in two institutions in Breslau. In one of the hospitals the proportion of placenta prævia to normal labor was 1 in 216, in the other 1 in 42—a remarkable difference. In 27.9% the placenta was central, in 61.6 lateral, in 10.5 marginal. The percentages of presentations were as follows: head 66.2, breech 1.8, footling 8, and transverse 24. Of the total 133 mothers, 8 died—5 from the direct effect of loss of blood, and 3 from fever or exhaustion after the first week; 27% of the children were born alive. As for management, the tampon, with

[10] Centralbl. f. Gynäk., No. 8, 1895.
[11] Ibid., No. 35, 1895.

the expectant treatment, was applied in 7 cases, rupture of the membranes with forceps in 9, forced labor in 1, and combined version in 115; in this latter category all the maternal deaths occurred. The cases, however, in which combined version was employed were all severe. One patient died from air in the veins 9 hours after labor.

Demelin[1] divides hemorrhage from faulty attachment of the placenta into 3 varieties. In the first labor has not begun. Here, if the flooding has been slight and has ceased, a skilled nurse should be constantly at hand ready with the tampon. When no assistance of this kind is available, the uterus should at once be emptied if the patient be strong with a good pulse. If she be weak from the hemorrhage, and therefore unable to bear so active a measure, the tampon should be introduced and maintained till the patient be stronger. In about 6 or 8 hours, as a rule, forcible delivery will be safe to perform. In the second class of cases labor has set in, but the cervix is but incompletely dilated. Then in lateral or marginal insertion of the placenta the membranes should simply be well opened if the vertex present and be well engaged. This maneuver is dangerous if the pelvis be contracted. In breech presentation, well engaged, one foot must be drawn down through the rent in the membranes. In any other presentation, or when the vertex or breech is prevented from coming well down, the dilating bag should be employed after rupture of the membranes, as the presenting part cannot in such a case press strongly enough on the bleeding surface. The tampon may also be needed. In complete placenta prævia, when the cervix is not fully dilated, the placenta should be perforated and the cervix dilated with the bags, the fetus being rapidly delivered if the patient be still strong. When she is weak and the pulse failing, the tampon must be applied till she has regained strength. If suddenly the child and the tampon are delivered together, so much the better. There remains the third class of cases. Here labor has set in and the cervix is completely dilated. To turn and deliver at once, or to deliver with the forceps if the head be well engaged, is the right course unless the patient be very weak from hemorrhage. In such a case, as before dilatation or labor, the tampon should be used. The head must be lowered, the extremities bandaged, and warmth applied. Rapid delivery must be effected, under ether, directly the patient has regained sufficient strength.

In the case of placenta prævia centralis Nijhoff[2] adopts the following method: As soon as the internal os admits one or two fingers the placenta should be carefully perforated, so as not to tear through the amnion at the same time. The amnion should then be separated as far as possible from the fetal surface of the placenta, and gentle friction made upon the fundus, so as to push the bag of amnion through the rent. The vagina should then be tamponed tightly with iodoform-gauze, and labor allowed to proceed. If the amnion be unexpectedly torn through, podalic version, followed by drawing down the hip into the lower uterine segment, should be performed. [We cannot recommend this procedure. It would be much more expeditious, and safer for both mother

[1] Arch. de Tocol. et de Gynéc., Nov., 1895. [2] Loc. cit.

and child, to immediately perforate the placenta in its entirety and deliver the child rapidly by podalic version. A distinct contraindication to the method exists, as Nijhoff himself admits, when the placenta is difficult to tear through.]

ABORTION.

[Much has been written upon the great danger of premature loss of the ovum to which all childbearing women are exposed, but, aside from the very decided stand that has been made by the better portion of the profession against the practice of criminal abortion, not only by so-called "specialists," but by women themselves, very little new has been added.] Foerster[1] emphasizes the importance of abortion as an etiologic factor in gynecology, and urges a more careful attention on the part of the general physician to the management of those cases that fall into his hands. The danger of quinin in pregnancy is again discussed by Coromilas,[2] who states that although in some cases quinin administered to pregnant women appears to have little oxytocic action, in others it has the power of exciting uterine contractions, more particularly in delicate, nervous, and anemic women. He has also observed that quinin administered during menstruation in some cases stops the flow, and frequently diminishes it. He relates the histories of 4 cases in which quinin apparently induced labor-pains, and concludes that during pregnancy and menstruation quinin should not be given in large doses, unless it be in conjunction with some narcotic that will act as a sedative upon the uterus. Titone,[3] in view of this action of quinin, would substitute for that drug phenocoll in pregnant women suffering from malaria. He has found that phenocoll has no action on the uterus. He gives it in doses of $1\frac{1}{2}$ grams, divided in 4 cachets, to be taken according to the Roman method—that is, 5, 4, 3, and 2 hours before a febrile paroxysm is due. He has used the drug in many cases with beneficial results, and has never seen disastrous consequences follow.

Rare cases of abortion are recorded by Haultain,[4] O'Reilly,[5] and Barcus.[6] Haultain describes a rare form of abortion in which there occurred the expulsion of the amniotic sac alone, the third instance of the kind that has come under his notice. The patients were in each instance about 3 or $3\frac{1}{2}$ months pregnant. No mention of such an anomaly is to be found in any of the standard text-books, except the American System of Gynecology and Winckel's Text-Book of Midwifery. The exact cause of this form of abortion is unknown, although Winckel is inclined to believe it to be the result of a simple accident, a tearing of the amnion from the chorion during expulsion. More probable is it that preexisting disease and death of the embryo has been present, rendering its attachment to the uterus less secure. This supposition is strongly supported by the specimen exhibited by Haultain. In the first case this is undoubted, there being no trace of embryo present. In the second case there was an excess of liquor amnii containing a large quantity of débris, and

[6] Med. News, Aug. 10, 1895.

an extremely feeble cord for the size of the embryo, while its placental end was represented by a thickened, smooth nodule, no trace of tearing being present. In the third specimen the embryo was free in the amniotic sac, unattached to the amnion. [Two facts are illustrated by these cases—namely, the possibility of the total absorption of the embryo, and, secondly, the continued secretion of the liquor amnii after the death of the embryo, although the hydramnios may have been the cause of the fetal death.] O'Reilly reports a case of hematocele supervening on an abortion. The effusion of blood took place into the subperitoneal tissue around the uterus. Three months later suppuration occurred, and the abscess discharged itself externally near the umbilicus, after which the patient made an uninterrupted recovery. [At least $2\frac{1}{2}$ months of suffering could have been avoided by an early abdominal section and evacuation of the exuded blood.] Barcus records the sudden death of a woman from shock due to a self-intrauterine injection of a solution of lead acetate to induce abortion. There were no wounds made by the catheter rendering it possible for air or fluid to have been injected into the uterine sinuses; hence the death must have been due to shock. Mann [1] reports 3 cases of perforation of the uterus after abortion, with prolapse of intestine through the rents. He urges care in the use of dilators after abortion, at which time the uterus is much more easily torn than in the nonpregnant condition. L. J. Mitchell [2] records a case of sudden death from air-embolism following an attempt at abortion. At the autopsy, performed 6 hours after death, the right ventricle was found to be filled with air and blood churned together. The pregnancy was 10 weeks advanced, and the membranes had been punctured and separated from the uterine cavity over an area of 5 cm. No bacteriologic examination was made; hence, the gas-producing bacilli are not excluded, but Mitchell concludes that the peculiar circumstances attending the death and the short interval between the decease and the necropsy would seem to preclude the participation of these germs.

In the study of the *diagnosis of abortion* probably the most important paper of the year is that of Ayers,[3] who states that the weak spot in the relations of our profession to the management of abortion is our want of accurate knowledge of the anatomy and physiology of the uterus, decidua, and fetal membranes, and particularly of the chronology of the membranes in the first 3 months of pregnancy. The advantage of an accurate knowledge of the growth of the ovum as a whole lies in the fact that when we can name the week of pregnancy, having secured the embryo in a partial abortion, we can decide far more scientifically what treatment the uterus requires than by simply resorting to the curet. It is necessary, for properly managing these cases, to know how the tissues are arranged at 4 weeks, 6 weeks, 8 weeks, 10 weeks, and 3 months.

At Four Weeks.—The decidua is much the most important membrane at 4 weeks' gestation. The reflexa is fully formed, but does not occupy more

[1] Am. Jour. Obst., May, 1895.

[2] Medicine, Feb., 1896.

[3] Med. Rec., Sept. 28, 1895.

than three-fifths of the uterine cavity. Consequently on introducing the finger within the internal os it would, after having passed the vera at that point, come in contact with a body like a polyp at a distance of a little over $\frac{1}{8}$ in. The ovum is about the size of a large hazelnut. The chorion is fully formed on all sides, with the exception of the normal bald spot, the size of a well-dilated pupil. The amnion, on opening the chorion, will be found to embrace the embryo, but not to have expanded to more than half the distance to the chorionic periphery. The embryo will be found lying free within the amnion and about the size of a small Lima bean. The little elevations that are to form the extremities appear upon the embryo. The latter is a little larger than a good-sized pea.

At Six Weeks.—The decidua is still prominent and important. The vera is unchanged, the serotina has grown and thickened, the reflexa is undergoing an atrophy that began in the fifth week. The latter is nearer to the internal os. The chorion has expanded to the size of a silver half-dollar and enjoys a luxuriant growth of villi. The amnion is nearer the periphery, but is still separated from it. The embryo has doubled in size, and its extremities show an appreciable length.

At Eight Weeks.—The chorion and remnant of the decidua reflexa fully occupy the cavity of the uterus. The amnion also occupies the entire cavity of the chorion. The fetus measures 3.5 cm., and has the hands and feet well outlined. The decidua, having grown thinner, is less apt to come away complete, particularly as the chorion is more apt to rupture, and by the collapse resulting make it doubly difficult for the uterus to separate and expel the membranes. If the chorion escapes from the uterus without rupture, it generally escapes alone, leaving the decidua behind. This decidua should be removed at once, and the best medium for its removal is the finger.

At Ten Weeks.—The fetus and partially formed placenta are now the prominent parts in the uterus. The temporary villi of the chorion have largely disappeared, also the reflexa, leaving a thin layer, composed of the amnion and chorion, to be felt should the finger be introduced within the cervix. The prominent characteristics of abortion at this time are expulsion of the fetus and umbilical cord alone; their expression with the amnion, which may or may not be unruptured, the cord having separated from the forming placenta at its junction with the latter. The placental tissue is apt to remain in the uterus for a varying time and cause hemorrhage, and to become foul-smelling. It should be removed soon after the expulsion of the fetus.

At Three Months.—The placental form is now well established, and the uterine contents behave much as they do at full term, with these differences, that the placenta is less firmly put together and is more firmly united to the uterus. There is danger, therefore, of masses of placenta being retained, even though much may be expelled.

As regards the **treatment** of abortion, Strouse[1] would limit the use of the sharp curet to cases of septic endometritis, and believes that douching is never

[1] Univ. Med. Mag., Oct., 1895.

of service. Jacub[1] advises that threatened abortion be treated by absolute rest, with opium or viburnum prunifolium. When hemorrhage occurs without dilatation of the os and cervix the antiseptic tampon is indicated. When hemorrhage is present and a finger can be inserted, the uterus should be emptied by the finger, accompanied by antiseptic irrigation. If hemorrhage is considerable and only partial dilatation is present, the finger is the safest instrument to complete dilatation. In many cases, if the patient be kept clean, the membranes and placenta will be expelled without interference and without injury. In all cases ergot should be used in daily doses during the first week. The use of the sharp curet is not encouraged, and vaginal douches after abortion should be given for positive indications only. Jacub calls attention to the fact that to the finger the placenta feels exactly like the endometrium, and that it is quite possible for the physician to imagine that the uterus is empty when the placenta is completely adherent. Michailowa[2] concludes from a trial in 5 cases that, contrary to the accepted opinion, viburnum prunifolium not only does not always prevent abortion, but sometimes even occasions it, or, at least, accelerates a miscarriage already commenced. [From a large experience in the use of this drug in abortion we are not ready to accept this statement. It has been most efficacious when employed in conjunction with an opiate.] Warman[3] recommends asafetida in obstetric work, and claims that it is most efficacious in reducing the hemorrhage of threatened abortion. Especially has it been successful in cases of habitual abortion (*abortio habitualis*), 5 instances in all having been observed by the author. The drug is administered in pills containing $1\frac{1}{2}$ gr. or in the form of an enema containing the tincture. In the habitual cases the dose at first is 2 pills a day, increasing to 10, the number subsequently being again reduced. No unpleasant symptoms are produced, but, on the other hand, the action of the bowels is very much assisted.

Hartmann and Toupet[4] have exhaustively studied the changes that nonseptic fragments of placenta may undergo when left attached to the uterine wall. These changes are—1. Simple sclerosis of the placental tissue; 2. Benign deciduoma; 3. Hydatiform mole; and 4. Malignant deciduoma. In all chorionic villi are to be detected by the aid of the microscope. By benign or innocent deciduoma is understood the true placental polypus and more sessile growths, in which there is distinct evolution going on in the chorionic villi and no sclerosis of the connective tissue. The growth does not, however, recur after thorough removal. The authors relate a case in which, as usual, the prominent symptom was frequent metrorrhagia. Legars and Lévi describe a very distinct case of placental polypus with the same symptoms. The malignant deciduoma which Hartmann and Toupet term "chorion-cell sarcoma," and the hydatiform moles are, in their opinion, related. In the latter, so long and so well known to the obstetrician, just as in the former, which appears to be a disease but recently recognized, the growth tends to invade and even perforate the uterine wall. In these graver as in the less serious changes in

[1] Monatsh. f. Geburtsh. u. Gynäk., Sept., 1895, Bd. ii. H. 3. [2] Med. Oboz., 1895.
[3] Therap. Monatsh., Jan., 1895. [4] Ann. de Gynéc. et d'Obstét., Apr., 1895.

retained placental tissue uterine hemorrhages are always an early and prominent symptom.

The Induction of Abortion.—Jeffé,[1] from a study of the literature of the last 10 years, fixes the indications for inducing abortion as follows: *Absolute Indications.*—1. Uncontrollable vomiting of pregnancy; 2. Incarceration of the gravid uterus; 3. Obstruction of the pelvic outlet by tumors or exudates; 4. Progressive and pernicious anemia; 5. Grave chorea. *Relative Indications.*—1. Great contraction of the pelvis, with the conjugata vera below 5 cm.; 2. Pulmonary emphysema, with signs of degeneration of the heart; 3. Nephritis; 4. Chronic heart-disease; 5. Other general diseases of the mother that would jeopardize her life at the time of delivery. He holds that a conjugata vera of 6 cm. and advanced pulmonary tuberculosis should not be regarded as indications for abortion; he does not think it just to sacrifice a future life for one that is "certainly lost." Garrigues[2] believes that the conditions that justify artificial abortion, apart from acute diseases, are, especially, serious pulmonary tuberculosis, severe valvular heart-disease, aortic aneurysm, carcinoma not amenable to radical treatment, chronic nephritis, severe affections of the nerve-centers, and present or threatened insanity. Ahlfeld[3] discusses the value of Müller's method for determining the indications for induction of labor by pressing the head of the child into the pelvic brim. While this method has advantages, it is not to be relied upon solely. Ahlfeld prefers to estimate carefully the period of gestation, to measure the length of the fetal body within the womb, to compute the length and weight of the fetus, and to combine these data with those given by palpation. It is also to be remembered that a fetal head which cannot be pressed downward into the pelvis can be brought through after version, the breech preceding.

As regards the method of the induction of abortion, Garrigues[4] dilates the cervix by conical hard-rubber and expanding steel dilators until there is room enough at least for a curet, but, if possible, for a finger besides; he then curets as long as anything comes away. Before scraping, the uterus is washed out with creolin, and afterward a quart of a 1% solution of that drug is passed through the uterus by irrigation. Drainage is not needed during the first 2 months; later the uterus should be packed with iodoform-gauze, which must be gradually withdrawn, so as to give the organ a chance of contracting well before the last of the packing is removed, from 4 to 6 days after the operation. Puech[5] believes that curettage of the gravid uterus should be placed among the classical methods for producing artificial abortion.

[It is now 3 years since Pelzer of Cologne first advocated glycerol-injections for inducing labor, and already sufficient data have accumulated to prove the extreme danger of such a procedure. Even Pelzer himself has abandoned it, because of the danger of maternal nephritis, and, in addition, he states that large doses of glycerol are apt to destroy the life of the child by exciting too

[1] Med. Neuig., No. 45, 1894. [2] Am. Gyn. and Obst. Jour., June, 1895.
[3] Monatsh. f. Geburtsh. u. Gynäk., Bd. i. H. 6, 1895. [4] Loc. cit.
[5] Ann. de Gynéc. et d'Obstét., Aug., 1895.

violent uterine contractions.] Hypes[1] in examining 33 reported cases treated by this method finds that 13 children were lost. Ferrari[2] concludes that glycerol injected into the uterus does not possess a constant and reliable action, nor does it produce a certain result; that it is dangerous, owing to the changes that it produces in the blood and kidneys; that it should not be used when the kidneys are diseased; and that death of the fetus may result from its employment.

Kufferath[3] describes a method [which cannot be pronounced as altogether new] for inducing premature labor in the later months of pregnancy. The neck of the uterus is fixed with a volsellum, and a glass cannula attached to an irrigating apparatus is passed through the internal os and made to press lightly against the membranes. The lower uterine segment is then irrigated at low pressure, and the membranes thus separated in the neighborhood of the internal os without the position of the child being altered, and without causing pain if care be taken that the fluid escapes easily. The fluid used by Kufferath was sterilized water containing a little boric acid in solution, and the quantity employed varied from 1 to 2 liters. He had successfully adopted this procedure in 15 cases, and claims that it is much more powerful and rapid than any other.

EXTRAUTERINE PREGNANCY.

[**Ectopic pregnancy** has claimed the attention of many obstetricians during the past 12 months, an unusually large number of interesting cases having been reported. This is probably the result of the increased knowledge of the subject the result of the extensive investigations that have been carried on during the last decade, so that cases formerly overlooked or treated as pelvic hematocele are now properly diagnosticated and treated.] The most scientific paper of the year is that of Pilliet,[4] who describes the researches which he has made in studying the changes that the uterus undergoes during **tubal gestation.** He finds that a true deciduous membrane forms within the womb in these cases. It is usually expelled at from 6 weeks to 3 months of pregnancy. Two conditions in these cases attract attention: the first is the characteristics of the deciduous membrane as found in the uterus, and the second the condition of the uterus after the expulsion of the decidua. So far as the first is concerned, the decidua found within the womb in cases of ectopic gestation is remarkably swollen and engorged. It resembles the normal mucosa but little. Upon the superficial aspect of the membrane there are abundant blood-vessels in a condition of engorgement, while the tissues surrounding them are somewhat edematous. In some places exudations of blood and serum may be observed. Some of these hemorrhages are the result undoubtedly of exertion and fatigue, and resemble the premature detachment of the placenta. In other places the extravasated blood is found to contain what resemble placental villi. [No true placental tissue can be formed in the uterine cavity in tubal gestation.] This decidua may be expelled in considerable quantities, or it may be

[1] Am. Jour. Obst., No. 61, Dec., 1895.

[4] Ann. de Gynéc., Oct., 1895.

gradually extruded with its cellular elements in an abundant serosanguinolent fluid. In the latter case its recognition is more difficult. This tissue resembles very closely the network of capillaries found in granulations and in sarcomatous tissue. The muscular tissue that underlies the basement membrane is also hypertrophied, undergoes involution slowly, but shows no signs of genuine inflammation. After the expulsion of the decidua the uterus presents many signs of parenchymatous metritis in the vascular lesions present in the dissection of muscular fiber by layers of embryonal cells. This condition may be traced to the peritoneum. When curetting is practised in these cases but little is removed, because the decidua has all escaped. New tissue gradually develops where the decidua has been removed, and the epithelium is slowly re-formed. The condition of metritis may persist for a long time; without the clinical history of the case microscopic examination would render it difficult to make a diagnosis. [From these studies it is easy to observe how readily the one condition present may be overlooked if the physician confine his attention to the condition of the uterus. Without a thorough examination of the pelvis, and without studying the clinical history of the case, the true diagnosis may readily be missed.]

Of equal interest with the foregoing is James Oliver's contribution on the extravasation of blood in tubal pregnancy.[1] He states that during the evolution of a natural pregnancy there results not only an augmentation in the size of the blood-vessels of the uterus, but a hypertrophy of the tissues of this organ generally. When, however, the fecundated ovum develops in the Fallopian tube, it seldom happens that any vigorous local growth is excited by its presence, although the blood-vessels in the involved tube become greatly enlarged. Apart from any intrinsic disease, the integrity of a blood-vessel depends greatly upon the manner in which it is supported by the surrounding tissues. When, therefore, the pressure exerted by the Fallopian tube against a growing ovum is insufficient to support the correlatively enlarged blood-vessels, they rapidly become thinned, and rupture with extravasation of blood takes place on the slightest provocation. When the developing ovum is located in the cavity of the uterus, we are accustomed to believe that accidental hemorrhage from the maternal vessels never takes place until after the fourth week of pregnancy. Whether this belief be correct or not, it is evident that in tubal pregnancy accidental hemorrhage from the vessels in the mucous lining of the Fallopian tube may occur as early as the seventh or the tenth day after impregnation. In ectopic pregnancy, therefore, blood may be extravasated from the maternal vessels before the chorionic villi become vascular—a phenomenon that happens during the third week of pregnancy when the chorion becomes incorporated with the allantois. The paroxysmal attacks of severe pain that are sometimes experienced in cases of tubal pregnancy are due to these effusions of blood, and, although the primary hemorrhage occurs always whilst the ovum is living, subsequent hemorrhage may nevertheless happen after this body has died. Rupture of the Fallopian tube itself, which has gradually become more

[1] Lancet, Dec. 7, 1895.

and more thinned, may be induced by the first or any succeeding extravasation of blood; and as this accident may occur as early as the fourth week of pregnancy, before the chorionic villi have begun to participate in the formation of a true placenta—for the ovum is everywhere placental at this period—the breech in the continuity of the tube is not, in all cases at least, attributable to a thinning at the placental site or to a penetration of the tube by the villous processes. A portion of the external hemorrhagic discharge—vaginal—which is observed in the early days of some tubal pregnancies comes directly from the ruptured vessels in the tube. [This paper is of considerable interest, as throwing some additional light on the etiology of the rupture in a tubal pregnancy.]

The relation existing between hematocele and extrauterine pregnancy is considered by Küstner,[1] who believes that the greater portion of these extravasations are due to ectopic gestation. Wyder has proposed making sure of the diagnosis by curetting the uterus and examining the material obtained for decidual membrane; but this method is not without danger, and negative evidence proves nothing. In cases of doubt it is, however, justifiable to aspirate the tumor through the vagina. When left to itself, the blood-clot coagulates about the periphery and remains fluid in the central portions, so that it can sometimes be shelled out of its capsule as if it were a cystic tumor. The tube is sometimes surrounded by the clot, sometimes free from it. The chorion can usually be found, but rarely the fetus.

According to Hofmeier,[2] the **diagnosis of etopic gestation** during the first 2 months is always difficult. Frequently there may be noticed a very marked pulsation in the affected side; the disappearance of this, the non-increase in size, as well as a gradual hardening of the tumor, point to a commencing disintegration, while an increase in the pulsation denotes a growth of the pregnancy. The removal of a piece of the uterine mucosa for investigation, which, in the early stages, gives the best means of diagnosis, is exceedingly dangerous; and in further advanced and doubtful cases this procedure is of no value. The pains, which are usually referred to tubal contractions and grouped under that name, are clear evidence, after the decidua has been thrown off, of the end of pregnancy.

Cripps[3] enlarges upon the chief points in the differential diagnosis between rupture occurring free into the peritoneal cavity, and when it occurs between the layers of the broad ligament, and when circumscribed in Douglas's pouch. When the sac bursts into the peritoneum, pain, though severe, is not so intense as when the bleeding is into the broad ligament. On the other hand, the general symptoms are graver, doubtless due to a larger amount of blood being lost. The abdomen is tender; it is resonant in front, and often there is considerable impairment of resonance, or even dulness, in the flanks. Careful palpation of the abdomen fails to detect any obvious tumor. On making a vaginal examination the uterus is movable and in the natural position. No tumor can be felt, but there may be some fulness in Douglas's pouch, convey-

[1] Aerztl. Rundsch., 1894, p. 817. [2] Centralbl. f. Gynäk., No. 31, 1895.
[3] Brit. Med. Jour., Mar. 28, 1896.

ing a doughy feeling to the finger, doubtless due to blood-clot. Examination of the rectum shows no stricture of the bowel.

If the rupture has occurred between the layers of the broad ligament, the sudden onset of the symptoms will be the same, but the pain seems to be more intense and lasting, with a well-marked paroxysmal character described by patients as like labor-pains. The patient generally shows signs of hemorrhage, though to a much less degree than in the intraperitoneal cases. On deep abdominal palpation a hard-feeling tumor may be found in one or the other side, rising out of the pelvis, though not to a great extent. Sometimes the swelling does not rise sufficiently to be obvious on abdominal examination. It is on examining by the vagina, however, that the more important points in the differential diagnosis are to be obtained, for in intraperitoneal rupture there is nothing abnormal to be felt, save perhaps the puffy swelling already alluded to in Douglas's pouch, whereas in the broad-ligament variety a hard swelling can be felt on one or other side of the cervix, partly filling the pelvic cavity. The tumor is firmly fixed, while the uterus, pushed to one side, appears to form the inner boundary of the swelling, and is attached to it. On examining the rectum a marked constriction is often present at about 4 in. from the anus; this is due to the rectal fascia, which passes round the bowel and is continuous with some of the broad-ligament fibers. Hence, if the broad ligament is pulled upon, as it is when distended by an effusion between its layers, the rectal fascia becomes drawn tighter, producing a ring-like stricture. When rupture occurs into Douglas's pouch, owing to the slight oozing which at first takes place, and which is the probable cause of the localized peritonitis that ultimately limits the effusion, there may be an absence of the sudden acute pain, followed by collapse which is so characteristic of the other two varieties of rupture already mentioned. The general history suggestive of a pregnancy may be present, together with some pain, though not of an acute nature, about the pelvis. An examination through the vagina discloses a swelling, perhaps the size of a cocoanut, and this lies behind the uterus in Douglas's pouch. The swelling is elastic, feeling like an ovarian cyst. The uterus, although its mobility is impaired, is not so firmly fixed as in the broad-ligament cases, and there is no stricture of the rectum.

Interesting cases of **tubal pregnancy** are reported as follows: Hofmeier,[1] 14 cases, 9 of which were operated upon, with 1 death; of the 5 cases not operated upon, 1 died of hemorrhage and 1 of septicemia, 2 were cured by spontaneous atrophy of the tumor, and 1 by the formation of a lithopedion; Hundley,[2] 2 cases; Bovée,[3] 1 case, in which all of the characteristic symptoms of the condition were absent; also[4] a case in which rupture followed the use of ergot; also[5] 1 additional case; Klein,[6] 1 case; Wawra,[7] 1 case; McColl,[8] 4 cases, 2 recovering without operation; Alfred J. Smith,[9] a case of ruptured tubal preg-

nancy, with hematosalpinx of the opposite side, in a woman 33 years of age with 4 children, the youngest $2\frac{1}{2}$ years of age; the hematosalpinx was not the result of tubal gestation; Cripps,[1] 10 cases, 1 of which, an abdominal pregnancy at 6 months, resulted fatally; F. W. Johnson,[2] 3 cases, in 1 of which there had occurred an external migration of the ovum, and in which hysterectomy was required; Doran,[3] 4 cases of early extrauterine gestation; Ingraham,[4] 2 cases; Henry,[5] 1 case; Foerster,[6] 7 cases, 4 of them being instances of tubal abortion; Malherbe,[7] a case which ruptured into the peritoneal cavity and projected through the inguinal canal in the sac of an old hernia, giving rise to all of the symptoms of a strangulated hernia; Elischer,[8] 2 cases cured by elytrotomy, both recovering, although 1 suffered for 3 days from iodoform-poisoning; Donald,[9] 1 case cured by vaginal celiotomy; Marx,[10] 1 case cured by the vaginal operation; Dührssen,[11] 2 cases treated by vaginal celiotomy; Condamin,[12] 5 cases treated by extirpation through the vagina; Schwarz,[13] the remarkable case of a patient who, when 2 months pregnant in tubal gestation, was taken with severe collapse; a tumor formed at the left of the uterus, and the patient gradually rallied from her collapsed condition. Two weeks later the hematocele ruptured into the bladder, and the woman began to void clots of blood and shreds of membrane. In 4 weeks the tumor at the side of the uterus could not be felt, while in 7 weeks the patient was convalescent and the uterus had undergone involution; Lanphear,[14] 3 cases, in 1 of which abdominal section was performed on the 15th day after rupture, and in another, which was complicated by an edematous myoma, hysterectomy was required, the patient perishing, however, 1 hour after the operation; Hall,[15] 6 cases, 2 of which perished shortly after operation; Moore,[16] 1 case with extraperitoneal rupture of the sac, the patient dying 13 hours after the operation. [According to Bland Sutton, only one-fourth of the cases of tubal gestation rupture extraperitoneally, and of those that do rupture in this manner almost all develop toward the anterior portion of the abdomen instead of along the posterior portion, as in Moore's case—hence the special interest attached to this case]; Barrow,[17] 4 cases; Breese,[18] a case in which 2 years after treatment by Apostoli's method, during which time the patient was an intense sufferer, the decomposing fetus was discharged per rectum, and 1 year later the sac was removed by abdominal section. [This is a good illustration of the danger attendant upon this most irrational and unsurgical method of treatment]; Nichols,[19] 1 case diagnosed before rupture and successfully operated upon; Baldwin,[20] 4 cases, 1

of which died 7 days after operation, which was performed 1 month after rupture of the gestation-sac, and in 1 of the others operation being performed 6 weeks after rupture; Rosenwasser,[1] a case in which an abdominal hematocele formed on the right side, the abscess-cavity extending from the iliac fossa upward and backward under the liver and well toward the spinal column, and resulting in a pleuropneumonia of the right side, beginning at the base and ascending to the apex; the patient ultimately recovered; George H. Noble,[2] a case in which operation was performed on the tenth day after the primary rupture, and hysterectomy was required on account of an unusual softening of the right broad ligament, resulting in a separation of that structure from the uterus throughout its entire height to a point below the internal os; the patient made a good recovery; Lauder,[3] 1 case; Grandin,[4] 3 cases; Jenks,[5] 1 case, in which was removed by abdominal section a distended, adherent, and painful tube containing an encysted 3 months' fetus; recovery was normal, though the patient was unmanageable and was out of bed every day after the day of operation; Jonas,[6] 3 cases treated by abdominal section after rupture, with recovery; Moffatt,[7] 1 case, diagnosed after rupture, successfully treated by abdominal section; and Boyd,[8] 2 cases.

More than the ordinary amount of interest is attached to the following reports: Folet,[9] a case of tubal pregnancy with twins, with retention for 15 years of a dead fetus at term. One fetus died at the second or third month of pregnancy; the other lived to term [which is an exceedingly rare occurrence in tubal pregnancy], the fetal sac with its contents remaining for 15 years in the abdomen of the patient without causing any illness. Then slight attacks of peritonitis, beginning with sharp pain, became frequent, and the patient entered the hospital for an operation. The fetal sac was adherent to the intestine, and a portion of the fundus could not be removed; it was accordingly sutured to the lower border of the wound. Complete recovery took place in 6 weeks after the removal of the tumor. The fetus was not a lithopedion; its tissues were flexible, but dense, and of a leathery consistence; they retained their normal structure; Le Dentu[10] records a case of twin tubal pregnancy, the two embryos, of 7 to 8 weeks' growth, existing in a single sac. Thus far, double bilateral twin pregnancies (7 cases in the thesis of Cestan and 4 in Brodier's observation) and twin tubal pregnancies in a double sac (3 cases, according to Cestan's thesis) have been recorded, but never before a case in which the embryos existed in a single sac; Bloom,[11] an abdominal section for double extrauterine pregnancy 13 weeks after abortion; both tubes were pregnant, and both had ruptured; the patient recovered; Ross,[12] a case of very early ectopic gestation with complete separation of the left tube from the uterine cornu at the time of rupture; abdominal section was performed under

ethyl-chlorid anesthesia. The portion of the tube containing the ectopic gestation was no thicker than an ordinary lead-pencil, and the pregnancy it contained could not have been of longer duration than about 2 weeks; the seat of the trouble was close to the uterine cornu in the isthmus of the tube, in the narrowest and least elastic portion; hence the early rupture. The patient died within a few hours. [This is possibly the earliest case of ruptured ectopic pregnancy recorded, 30 days being the earliest hitherto noted]; Walther,[1] a case of ectopic and entopic pregnancy with double uterus, the patient being 35 years of age; the tubal pregnancy was situated on the left side and was associated with a pregnancy in the right half of an ill-developed uterus of 3 months; in the left tube there was a hematoma; the patient aborted on the third day after operation; in the right half of the uterus were found the placenta, cord, and membranes, while upon the left side a thick deciduous membrane was present; the patient made a good recovery; T. E. Mitchell,[2] a case of simultaneous uterine and extrauterine gestation in a woman of 30 years, with 1 child 1 year old. Operation was not performed, and the patient died 3 days after a 5 to 6 months' fetus was extracted from the uterus by version. Necropsy revealed an adventitious sac behind the left broad ligament, to the posterior surface of which the placenta was attached. The fetation had been primarily tubal, rupture occurring 4 months prior to death. The fetus was slightly smaller than its uterine fellow; Moseley,[3] an interesting case of twin pregnancy, 1 fetus being intrauterine and the other extrauterine (tubal); the woman was delivered of her first—a 7 months' child—in March, 1895. Her menstrual flow returned in May, and recurred normally for the next 3 months. The September period was missed, and about the middle of November she began having irregular bloody vaginal discharges, together with local pain, followed on November 27th with a fainting-spell. Irregular bleedings continued until December 6th, when examination revealed the uterus enlarged to the size of 3½ months of pregnancy, and the right tube a sausage-like mass about the size of an ordinary round 2-ounce bottle, and having a moderate amount of elasticity. Operation the next day revealed the abdominal cavity filled with fluid and clotted blood; the right tube was ruptured in its outer third, and attached to its inner surface was an umbilical cord, at the other end of which was a fetus floating in the abdomen. This was removed. The patient died 48 hours after admission to the hospital. On opening the uterus, which was soft, friable, and baggy, another fetus, *a duplicate of the first*, was found attached near the opening of the left tube. In the left ovary was found a recently ruptured Graafian follicle. The right ovary was not found, but it seems probable that the extrauterine fetus was the result of impregnation of an ovum from this ovary, while the intrauterine was from the left. [The diagnosis of twin intrauterine and extrauterine pregnancy must be most difficult, especially in its earlier stages. Gutzwiller says there are no diagnostic signs, and Schrenck states that there are 43 cases recorded, in only 3

[1] Zeit. f. Geburtsh. u. Gynäk., 1895, Bd. xxxiii. H. 3.

[3] Am. Jour. Obst., May, 1896.

of which was a correct diagnosis made]; Ross,[1] a case of ectopic gestation occurring twice in the same patient at an interval of $4\frac{1}{2}$ years; Ross publishes a table of 5 similar cases, all he has been able to find. [A similar paper was presented by McKelway in 1893 at the Milwaukee meeting of the Am. Med. Assoc., in which he tabulates a number of well-authenticated cases of repeated extrauterine gestation, including 1 occurring in his own practice and 1 in that of Dorland]; Dunning,[2] a case of ruptured interstitial pregnancy; and Gebhardt,[3] the same; Ahlfeld,[4] a case of sarcoma deciduocellulare with tubal gestation, in a single girl of 17 years, resulting fatally; and Hoepfl,[5] a case of cornual pregnancy cured by operation. Wendler[6] describes what he considers a unique case of extrauterine pregnancy occurring after vaginal hysterectomy. At the operation the right ovary was not removed and the tube was drawn down into the vagina. Menstrual molimina had appeared every month after the operation, and their cessation had led to an examination. A 6 to 8 weeks' old fetus was found occupying the vaginal end of the tube. The tube was dilated, and its contents, consisting of fetal membranes and chorionic villi, were removed by a curet.

Tubal abortion is discussed by Muret[7] and Prochownick.[8] The latter remarks that, anatomically, a tubal pregnancy differs from that of the uterus in that no true decidua is formed. The chorionic villi penetrate the mucous membrane of the tube and enter the muscular coat, forming a kind of serotina. The newly-formed vessels rupture easily, causing hemorrhage, which leads to the death of the fetus and the accidents usually following an ectopic pregnancy. The cases may be classified as abortions from the ampulla; abortions from the tube proper; rupture of the tube and the formation of a mole. Two or more of these conditions may be combined in the same specimen. Abortion from the ampulla occurs when the ovum has formed its attachment to the tube near the abdominal end. The act is partly passive, due to the hemorrhage forcing out the ovum, and partly active, due to muscular contractions. The fimbriæ, which are adherent about the end of the tube, give way; the ovum is gradually forced down, and finally is cast out into the abdominal cavity. If the end of the tube is adherent or any obstruction occurs which prevents the casting out of the ovum, the tube is liable to rupture. Ampullar abortion is not frequently met with in the operating-room, but undoubtedly many cases occur and recover without surgical interference. Abortion from the tube proper is not of frequent occurrence—8 cases out of 24 are reported. In all of these the placental site was near the uterus and on a part of the tube covered by peritoneum. In every case there was an hematocele about the abdominal end of the tube, containing blood and chorionic villi. The abortion is begun by a hemorrhage taking place into and about the ovum. Owing to the resistance

of the uterus, the constantly increasing hemorrhage pushes the ovum toward the abdominal end; and this action is augmented by contraction of the tube. The farther the ovum is situated from the ampulla, the greater the mechanical difficulty of tubal abortion.

Muret states that if the abortion be incomplete, part of the ovum is retained in the tube and a tubal mole is formed. The symptoms of incomplete tubal abortion are tubal colic, the expulsion from the uterus of decidua without chorionic villi, and repeated attacks of intermittent pain with symptoms of internal hemorrhage. Abdominal section is always indicated for this condition.

Abdominal Pregnancy.—Cases of secondary abdominal pregnancy are recorded as follows: Mann,[1] 2 cases, 1 of which was in reality a pregnancy in one horn of a double uterus; the patient advanced to term, missed the labor, and the fetus was not removed until 8 years afterward, at which time a foul-smelling fetus was removed from a large sac that was closely adherent to the intestines; the patient recovered; in the second case the fetus had been retained in the abdominal cavity for 13 years, and when removed was somewhat shrunken and mummified, but not decomposed; the patient's recovery was uninterrupted; Tóth,[2] a case of rupture of the sac in the third month; the fetus continued to grow in the abdominal cavity until its death in the 36th week of pregnancy; an operation was performed 10 weeks later, and the primary condition found to have been a tuboovarian pregnancy; there was absence of fever; Pinard,[3] a case of extrauterine gestation at term cured by abdominal section; a living child was extracted, but the placenta was left *in situ*, the opening of the cyst being sutured to the abdominal wall and the cavity being packed with gauze; the patient recovered; Thomson,[4] 2 cases; in the first the ovum died at 6 months, and began to be discharged by ulceration into the vagina; incision and extraction of the ovum with its appendages were followed by cure; in a second case, in the last month of pregnancy, the ovum opened the abdominal wall by ulceration, causing in the process a fistula into the large intestine, which was subsequently closed by operation; Steltner,[5] a case in which the fetus lived nearly to full term, when it died; it was then carried by the woman for 12 years; at the end of 10 years the sac ruptured into the bladder and cystitis followed, and 2 years later a tumor of the right kidney—a hydronephrosis—resulting from temporary occlusion of the ureter following the contraction of the sac, which was adherent to the base of the bladder, was discovered; abdominal section was performed and the cyst evacuated and packed; the patient recovered; Reismann,[6] a case of tuboabdominal pregnancy with delivery of a living child at term; the gestation-sac consisted anteriorly of the uterus, posteriorly of peritoneal adhesions, while the broad ligament formed the right side. After extraction of the child there was profuse hemorrhage, arrested by removal of the placenta, which was attached to the peri-

[1] Buffalo Med. Jour., Aug., 1895.

[6] Ibid., No. 1, Jan. 4, 1896.

toneum of the culdesac and overlying the sacrum; the membranes were firmly adherent to the posterior uterine wall; after their partial detachment severe hemorrhage began, which could only be arrested by the removal of the uterus; after an attack of phlegmasia in the left leg the patient made a good recovery; the child was dolichocephalic, and showed an arcuate depression on the posterior portion of the frontal bone and the anterior portion of the parietal bone of the right side. The right ocular fissure was wider than the left, and the right angle of the mouth lower than the left. The right upper extremity was flexed at the elbow to a right angle, positive and rigid; the right hand was flexed inward and to the ulnar side; the four fingers were strongly flexed across the thumb. The right lower extremity was rotated inward and bent at the knee-joint to an obtuse angle; the right foot was in equinovarus, and the toes hyperextended. The head was flexed constantly to the right and drawn backward. The right sternocleido muscle was hardly to be felt, while the left was prominent and thick. Reismann concluded that this condition was due to cerebral spastic hemiplegia from compression of the skull in its cramped situation, the seat being in the central convolutions; Chase,[1] a case of tubal pregnancy, with primary extraperitoneal rupture into the broad ligament and secondary intraperitoneal rupture at the fifth month with fatal hemorrhage; Handfield-Jones,[2] a case of extrauterine fetation with operation near full term, the child living, but the mother perishing of sepsis 3 weeks after delivery; Eagleson,[3] a case of abdominal pregnancy at full term, with rupture of the sac and death of the fetus; the patient was 36 years of age and in her second pregnancy, the first occurring 17 years before. Pregnancy began in February, 1894, and on May 13 she suffered from severe uterine and abdominal pains, accompanied by profuse hemorrhage which continued for 4 or 5 days, and during which time a membranous cast of the uterus was expelled. Labor occurred in November, and was accompanied by uremic convulsions. Abdominal section was performed and a macerated fetus removed. The sac was readily removed, there being but few adhesions to the intestines, and these being easily separated; the placenta was firmly attached to the top and posterior surface of the uterus, and to the right broad ligament; the principal nutrient vessel of the placenta, as large as a small lead-pencil, came from the under surface of the mesentery of the ilium; commencing peritonitis was present, but the patient made a good recovery; Corus,[4] a case in which the fetus survived until the seventh month, and at the fourteenth month was spontaneously discharged per rectum, the patient dying from exhaustion on the ninth day after the escape of the fetus; Kaan,[5] a case in which a dead fetus was secured, the patient being a woman of 36 years, in her third pregnancy, the last pregnancy ending in a miscarriage 18 months previously. Rupture of the tubal pregnancy had probably occurred in June, 1895, but was unattended with collapse. Labor occurred in December, the

[1] Brooklyn Med. Jour., May, 1896.
[2] Lancet, Oct. 19, 1895.
[3] Jour. Am. Med. Assoc., No. 8, 1896.
[4] St. Louis Clinic, Apr., 1895.
[5] Boston M. and S. Jour., Apr. 30, 1896.

fetal heart-sounds being audible. Abdominal section was performed, the dead fetus extracted, the placenta clamped with large forceps, and the sac packed with gauze. The mother did not recover from the shock, and the autopsy showed the sac in the median line, evidently in the left broad ligament, entirely covered by peritoneum; the uterus was pushed downward, forward, and to the right. The sigmoid flexure ran across the top of the mass. The sac contained the placenta and about half a pint of postmortem clot. The uterus was enlarged and its walls thickened; W. R. Wilson,[1] a case of abdominal pregnancy that progressed to term in a colored woman 26 years of age. Abdominal section was performed and a dead fetus lying in a transverse direction extracted; hemorrhage could not be controlled, and the patient died in a little more than an hour after the operation. Necropsy revealed the amniotic sac adherent to the intestines, and the placenta distributed over the pelvic and abdominal viscera on the right side. The right tube and ovary were incorporated in this mass. Kollock[2] removed by abdominal section, from a woman who had gone 4 months beyond the normal term of pregnancy, an enormous fibroid tumor of the womb and a 10-pound macerated fetus which was surrounded by a large amount of offensive purulent fluid. The placenta lay in the right hypochondrium, was adherent to the sternum, and was removed with much difficulty and with excessive hemorrhage, which was finally controlled by packing the cavity with 6 yards of gauze and 3 of towelling. The patient did well for a month, and then died suddenly from intestinal obstruction. The autopsy showed a normal uterus and normal ovaries. The pregnancy had originally been left tubal, and had ruptured when about the size of an orange. The fetal sac had developed between the abdominal wall and the omentum. There were no intestinal adhesions, except one small band which had strangulated a loop of small intestine and caused the fatal termination.

Ovarian Pregnancy.—The following case, reported by Larsen,[3] is one of such rarity as to merit full mention: The patient was 33 years old and previously healthy. Her menses began at 20, and were regular except on one occasion, when 1 or 2 months were missed. A profuse flow was exceptional. She last menstruated in the beginning of August, 1891. Immediately after this she was seized with cramps, vomiting, and some pelvic pain. Three months later she had retention of urine, at which time, on examination, a uterine pregnancy at 3 months and enlargement of the right ovary were diagnosed. During the remainder of her pregnancy the patient's condition was good. Motion was felt by the middle of December, and on the 10th of the following April there were severe shooting pains accompanied by some hemorrhage and the passing of a firm lump the size of a hen's egg. Motion ceased at the same time. A thin, light, sanguineous discharge continued from the vagina, and at every return of the menstrual epoch this discharge acquired the appearance of the menstrual flow; otherwise the patient's general condition was good. On the 22d of September the diagnosis was made, under

[1] Am. Gynæc. and Obst. Jour., May, 1896. [2] Medicine, Feb., 1896.
[3] Centralbl. f. Gynäk., No. 28, 1895.

anesthesia, of a dead fetus retained in the uterus. Upon dilatation of the cervical canal, however, the body of the uterus, which on palpation could not be differentiated from the tumor, was found to be empty. On September 27th abdominal section was performed, with extirpation of the tumor, which was attached by a single rectal adhesion, though otherwise freely movable in the abdominal cavity, and united to the uterus by the right tube and broad ligament, which were also tied off. The right ovary could not be seen and the left tube and ovary were normal. Convalescence was uneventful. Upon opening the fetal sac a quart of chocolate-colored, thin, and very flocculent fluid, with a macerated, flattened, and apparently fully-developed fetus, placenta, and cord, were found. The placenta was attached to the posterior wall of the sac, while the anterior wall was adherent to the broad ligament, though this was easily separable except at the upper and outer part. At this place it was immediately continuous with the fetal sac, and this in turn was firmly attached, for a distance of 4½ cm., especially thick at the under part, to the posterior surface of the tube. The inner and upper part of the sac, near the uterine end of the tube, was also firmly united to the posterior surface of the ligament by a small adhesion. The portion of the tube that was removed measured 10 cm., and was much dilated. In the broad ligament could be seen three branches of the internal spermatic artery, the middle branch going to the fetal sac, which was also supplied with branches from the outer ones. The posterior surface of the sac was as thin as paper, while the anterior was fibrous in character and studded with the open mouths of the torn vessels; it was about 8 mm. in thickness.

The microscopic examination of the anterior wall showed here and there small groups of follicles with a distinct membrana granulosa, and in several of these appeared more or less well-preserved ovules with germinal vesicle and germinal spot.

Treatment of Extrauterine Pregnancy.—[Notwithstanding the general condemnation of any method of treatment of extrauterine gestation other than the surgical, we occasionally find some man of considerable standing advocating an obsolete method. These revivals, fortunately, are of but short duration.] Thus, in the Section for Obstetrics and Gynecology of the recent Congress of German Naturalists and Physicians, Prochownick[1] advocated the treatment of ectopic pregnancy during the first months by means of injections of morphin instead of by operation. He reported 4 cases successfully treated by a single injection through the vagina of from gr. ½ to gr. ¾ of morphin into the intact gestation-sac without aspiration. In 3 of the cases the pregnancy had not passed the twelfth week; in the remaining 1, which was complicated by gonorrhea, this period had been passed, and in this case also an abscess formed that discharged through the rectum. In a fifth case the injection was made through the anterior abdominal wall, and the sac was infected by the needle passing through an adherent loop of bowel; septicemia developed, abdominal section was required, but recovery ensued. It is

[1] Deutsch. med. Woch., 1895, No. 40, Suppl. No. 25, p. 170.

important to refrain from aspiration and to make but a single injection. The operation is contraindicated if the twelfth week has passed, if abortion is in process of occurrence, and if chronic gonorrhea or acute perimetritis exist. The vaginal is the only safe route of injection. [We may safely say that there is no safe route for such an operation, and even if fetal death be assured the woman is subsequently subjected to all of the dangers of sepsis during the process of absorption—if this should fortunately occur—or, more probably, to the danger of a secondary abdominal section. The primary section is by far the preferable and safer mode of treatment.]

Dührssen, Condamin, and others have performed vaginal celiotomy in a number of instances for the relief of this condition, and earnestly advocate this method in cases in which the pregnancy is not advanced more than 3 months. They claim that the shock is less than from abdominal section, while the result is equally and, possibly, more satisfactory. A case of ectopic pregnancy successfully operated upon by the vaginal method is reported by Reynolds:[1] A fetus of the lithopedion type, about the size of a 3-months' gestation, was found; fetus, placenta, and cord were removed intact. [The operation, however, is more difficult than abdominal section, and the same objections are applicable to it as to the operation for any gynecologic condition.]

LABOR AND THE PUERPERIUM.

Statistics.—Among the interesting statistics from large institutions mention should be made of the reports of Jardine[2] and Norris.[3] Of 2161 cases of labor attended during 4 years at the West End Maternity Hospital, Jardine states that there were only 3 which could not be delivered at full term without sacrificing the child. The fatal cases were 10. There were 5 cases of placenta prævia, all successful except 1 that died before assistance could be reached. Of 9 accidental hemorrhages, 8 were successfully treated. There were 9 postpartum hemorrhages, all successfully treated, and 2 cases of eclampsia, both recovering. In puerperal sepsis the practice of douching with mercuric chlorid (1 : 2000) was followed. Norris's report included 500 consecutive deliveries at the Preston Retreat since Jan. 1, 1894. There was 1 death from chronic Bright's disease, which made the mortality for this period $\frac{1}{5}\%$. There were 3 cases of eclampsia, all recovering; 1 case of placenta prævia; and 1 of premature detachment of the placenta, the child perishing, but the mother recovering; 2 mild cases of phlegmasia alba dolens; there were 11 cases of sapremia. Of the private statistics, the most interesting are those of Dr. James Ross of Toronto, reported by his son, J. F. W. Ross,[4] and consisting of an analysis of 6777 cases attended between the years 1852–92. The youngest mother attended was a girl of $15\frac{1}{2}$ years, and the oldest a woman of 50 years. 39 mothers perished, or 1 in $173\frac{30}{39}$, 7 dying from puerperal sepsis; there was 1 case of uterine rupture; 411 children were lost,

[1] Am. Gynæc. and Obst. Jour., May, 1896.
[2] Edinb. Med. Jour., Apr., 1895.
[3] Am. Gynæc. and Obst. Jour., Feb., 1896.
[4] Am. Jour. Obst., Sept., 1895.

or 1 in $16\frac{201}{411}$; there were 7 cases of brow-presentation, 25 of face, and 35 of transverse presentation. Of twin cases there were 106, or 1 in $63\frac{99}{106}$; there was 1 case of triplets, the children being all females, presenting by the breech. There were 18 cases of placenta prævia, 1 patient and 15 of the children dying. Eclampsia occurred in 11 cases, the patient dying in 2 cases, and 2 of the children perishing. In 22 cases there was prolapse of the cord. The forceps was used 491 times, or once in $13\frac{394}{491}$ cases. Venables[1] records 1000 cases of confinement. In this number uterine hydatids occurred once, and tubal pregnancy once. There were 4 cases of placenta prævia and 3 of eclampsia; there were 3 cases of face-presentation and 2 transverse cases. The forceps was used in 41 cases. Sawyer[2] reports 270 cases of labor with 1 death (from uterine rupture). Staples[3] records 1092 cases personally attended during the past 33 years. There were 18 cases of twins in this number. [Much valuable statistical information is lost in many instances by a failure to systematically record the points of vital interest occurring in an extensive obstetric practice.]

Asepsis in Labor.—[The importance of asepsis in the practice of obstetrics is rapidly becoming more generally appreciated, as is indicated by the large number of papers upon this subject. The methods adopted by the various maternity institutions are practically the same, with here and there some innovation that may or may not still further contribute to the safety of the patients. The most practical suggestions that have been gleaned from the literature are as follows:] Lusk[4] advocates, in order to have as complete asepsis as possible, removal of all the hair from the external genitals. In regard to the employment of the douche afterward, he considers that it is not only unnecessary, but extremely harmful, as it washes away the natural secretions that prevent the germs from developing. Lefour[5] is in the habit of having all pregnant women admitted to the lying-in hospital of Bordeaux stripped nude and bathed in soap and water containing 250 grams of sodium carbonate; they are then dressed in sterilized garments and sent to the dormitory. This bath is repeated every few days until confinement. At the onset of labor, the patient being in an aseptic condition as far as is possible, Stuart[6] is in the habit of administering a vaginal douche of Tavel's solution (made of powders of dried sodium carbonate and sodium chlorid, 2.5 and 7.5 parts, respectively, per 1000), to which is added 1% of phenosalyl.

The value of the various antiseptic agents has been determined more accurately by various observers. C. M. Groth[7] gives the statistics of the Southern Lying-in Hospital of Stockholm, where, since the last death from puerperal fever, 4000 women have been delivered, the conditions leaving nothing to be desired. For the past few years the strongest solution of lysol, the antiseptic used, has been 1% externally and 0.5% for injections. The students in mid-

wifery pay great attention to the study of external manipulation in order to restrict as much as possible internal maneuvers. Forceps was applied on account of insufficient labor-pains before the introduction of antiseptics, 24 times in 1000 cases; after the introduction of antiseptics, 18 times per 1000; during the first year in which lysol was used, 5 times; during the past 2 years, 12 times per 1000. Ahlfeld and Vahle[1] describe experiments made to ascertain the value of alcohol as a practical disinfectant in obstetric practice. The results obtained by disinfecting the hands with alcohol have been variously assigned to the solvent properties of alcohol upon the fatty tissues, thus allowing mercuric chlorid and other antiseptics to come into immediate contact with bacteria contained upon the fingers. Others have asserted that alcohol does not destroy bacteria, but coagulates the epithelia of the skin, thus hardening them without preventing the passage of germs. It has been found, however, that alcohol destroys bacteria, but that its most efficient action is exerted upon microorganisms that themselves contain water or that are found in tissues containing water. By experiment Ahlfeld found that alcohol does not act simply by dissolving fatty substances upon the fingers, because ether, which is a better solvent of fat, is not so efficient as an antiseptic. Experiments with septic germs proved that alcohol exerts a direct influence in destroying virulent streptococci. Upon dried tissues containing bacteria, and upon bacteria from which water had been removed, alcohol exerted but feeble influence. An experiment was made with amniotic membrane to determine the influence of alcohol upon such tissues when wet and when dry; the result demonstrated in a striking manner the prompt action of alcohol when the membrane was moistened. Experiments upon the hands of attendants and nurses demonstrated clearly the value of alcohol as a disinfectant. Chinosol was recommended by Kossmann as a valuable antiseptic in obstetric practice. Other authors have investigated his claims, and do not share his enthusiasm. Thus, Witte[2] states that Kossmann's experiments were incomplete, since the germicidal power of chinosol was tried only upon the staphylococcus pyogenes. He also finds, in opposition to Kossmann, that chinosol is very irritating, and that its action is accompanied by burning sensations. It has marked astringent properties, and thus is objectionable for vaginal douching. Ahlfeld and Vahle find that the germicidal power of chinosol is slight. In 48 experiments the hand became sterile only once. Cultures of the staphylococcus pyogenes grew in 3% solution of chinosol. It was further found that its poisonous properties manifested themselves mainly in disturbed kidney-action. Wells[3] calls attention to the superior value of creolin as an antiseptic for obstetric use. [While generally doing no harm, it now is becoming recognized that these so-called obstetric antiseptics are of little practical service. The plentiful use of boiling water answers every purpose to much better advantage.]

The methods of preparing the hands for attendance upon labor are many. Ahlfeld[4] recommends the following: The nails should be cut short, trimmed,

[1] Deutsch med. Woch., No. 6, 1896.
[2] Centralbl. f. Gynäk., No. 9, 1896.
[3] Phila. Polyclin., iv. 1895.
[4] Deutsch. med. Woch., No. 51, 1895.

and smoothly polished, and scrubbed for 3 minutes with soap, brush, and warm water; then the hands should be washed in clean boiled water; they are then carefully rubbed in 96% alcohol with a piece of flannel, especial care being taken that the alcohol enters well under the nails. Reinicke[1] first cleanses the hands with hot water, soap, and brush for 5 minutes; they are then brushed from 3 to 5 minutes in 90% alcohol, and afterward in an aseptic fluid, preferably mercuric-chlorid solution.

The Conduct of Normal Labor by External Examination Only.—Leopold and Orb[2] report the results of the conduct of normal labor by external examination only in 1000 cases. Errors in diagnosis occurred in 65 (6.5%). Fifty-four of these were in occipital presentation, 2 in brow, 2 in breech, 1 in twin gestation; while in 6 cases of face-presentation an error was made in diagnosticating the entire number. In 168 cases contracted pelvis was diagnosticated. The writers show by statistical comparison of series of cases that palpation may be relied upon to determine a most important point—namely, the presence or absence of descent of the fetus into the pelvis.

Rectal Examination of Pregnant and Parturient Women.—Beckman[3] claims that he has tried this method with great success in 100 parturient women, the details of the pelvis and cervix being easily made out. The length of the pregnancy and state of the bladder could not be determined in 7% of the cases, and the fontanels and sutures could not be felt in 28%, but this was less important, since the position of the fetus could easily be detected by external examination, and especially by auscultation. It was always possible to distinguish the occipital from the frontal portion of the head. The advantage of rectal examination, he urges, is that infection through the genitals is avoided, the only objection being that sometimes examination through the vagina may become necessary, and that infection may occur through the examining finger. [The method is an uncleanly one and will never become general.]

The Height of the Fundus Uteri at Various Stages of Labor.—Fothergill[4] has measured the distance from the fundus uteri to the upper margin of the pubic joint during the first stage of labor and during the second stage. He also measured the breadth of the uterus in the different stages, as well as its length. His results showed that the fundus rises $\frac{3}{10}$ in. before birth; the uterus becomes narrowed laterally $1\frac{1}{10}$ in. before labor ends, while the measurement from the fundus to the pubes lessens 1 in. before birth. The length of the parturient canal is not shortened before delivery; as the child passes through the uterus into the vagina the womb grows narrow, while as labor advances the uterus is contracted anteroposteriorly. The cubic contents of the uterus are lessened. The fundus does not sink before the birth of the head.

The Maternal and Fetal Blood at Birth.—Elder and Hutchison[5]

[1] Arch. f. Gynäk., 1895, Bd. xlix. H. 3.
[2] Ibid., 1895, Bd. xlix. H. 2.

[5] Ibid., Aug., 1895.

reported before the Edinburgh Obstetrical Society the result of a series of observations on the blood of mothers and healthy children immediately after birth. They obtained the blood from the umbilical cord when it was cut, and from the lobe of the mother's ear during the latter part of the first or during the second stage of labor. They arrived at the following conclusions: (1) The blood of the newly-born child is relatively richer in red corpuscles than that of the adult by 350,000 to 500,000 per cmm. (2) For a short time after birth—up to about 2 days—the red corpuscles seem to increase in number. This is probably due to the fact that the total volume of blood is less, from the fluid lost from the body during this time being in excess of that absorbed. Thus concentration of the blood is produced. After the second day or so the red corpuscles gradually decrease. (3) The number of red corpuscles varies much more than in adults, probably because of greater variations in the total volume of the blood. (4) At birth there is always present a considerable number of nucleated red corpuscles. They vary, however, in number in different cases. (5) About the sixth month of intrauterine life the number of nucleated red cells is very much greater than at birth. They probably rapidly decrease in number during the latter months of pregnancy, and altogether disappear from the blood in a few days after birth. (6) The blood of the newly-born child is relatively much richer in hemoglobin than the blood of the adult. (7) The individual red corpuscles are richer in hemoglobin than those of the adult. (8) The blood of the mother at parturition is anemic. (9) In any individual case the blood of the mother is considerably poorer in red corpuscles per cmm. than that of her child, and it is still more deficient in hemoglobin. (10) Both the blood of the mother and that of the child contain a larger number of white corpuscles than normal adult blood. The blood of the mother may be quite as rich in white corpuscles as that of the child. (11) The blood of the child contains a distinctly larger proportion of lymphocytes and a distinctly larger proportion of neutrophile leukocytes than the blood of the adult; the number of eosinophile cells seems to be slightly deficient. (12) At the sixth month this excess of lymphocytes is probably even more marked than at birth; they probably decrease during the later months of pregnancy. (13) After parturition the number of white corpuscles in the blood of the mother (at least of those who suckle their children) decreases markedly in a few days.

The great difference between the constitution of the blood of the mother and that of her child would altogether dispose of the idea of any mixing of their bloods, even if histologic investigation had not already proved that this did not occur. There can be no doubt that the excess of hemoglobin, and consequently of the preponderance in oxygen-carrying power, on the part of the blood of the child, must be one of the most important means by which its metabolism is carried on as it is. When it is remembered that the child's blood can only be oxidized indirectly through the blood of the mother, and is consequently in a possibly comparative state of cyanosis, it can be seen that a great quantity of red corpuscles is valuable for the child to compensate for

this. Handfield-Jones[1] lays stress upon the fact that the heart-muscle after labor is left in a tired and exhausted condition; also that the emotional effects of excitement, and possibly fear, must tell unfavorably on the nervous supply of the organ; there is also at this time the existence of a suddenly diminished arterial pressure and increased venous pressure, predisposing to cardiac syncope. During the process of involution, likewise, there occurs a fatty degeneration of the hypertrophied cardiac muscle, and this process is occasionally carried too far. Williams and Cutler[2] report their observations as follows: They consider the low rate of the pulse after delivery to be exaggerated in many text-books. They found that in 11% the pulse remains stationary, while in 13 it was increased after the end of the third stage. It was found that the length of labor exerts some influence upon the pulse, and also that chloroform makes the pulse higher after delivery. In 19 cases of postpartum bleeding the pulse rose on the average 19 beats per minute; the tension is usually above normal during labor, and, should it be below normal, there is danger of bleeding. Respiration is slightly slower after delivery. The average temperature during the lying-in state was between 98° and 99° F. Rupture of the perineum did not influence the temperature, unless septic infection occurred.

Analgesia in Labor.—Pleas for the use of anesthetics in labor are offered by Simmons[3] and Earle.[4] Earle prefers chloroform, which may be used advantageously not only at the close of the second stage, but at the close of the first as well. It eases the patient, relaxes the perineum, and does not affect the fetus even in prolonged use. In the first stage Simmons employs chloral with excellent results. He has also frequently employed morphin in the first stage of labor with gratifying results.

The Third Stage of Labor.—Ahlfeld[5] proposes some more definite nomenclature for the proceedings in the period of the after-birth. This is intended to clear up and make definite the terms used with reference to the third stage of labor, when operative interference becomes necessary. He proposes to define as *Credé's procedure* the gentle friction of the uterus or its control immediately after the birth of the child, so as to express the placenta, by compression, into the vulva as soon as one or more pains come on. This pressure is *Credé's manipulation.* So as to differentiate this from the pressure by means of which a placenta lying in the vagina is expressed, Ahlfeld designates the latter as *expressio placentæ* or *squeezing out of the placenta.* Ahlfeld defines *expectant methods* as those in which the uterus is not rubbed, and, where possible, is not touched at all. He also differentiates *Removal* of the placenta from the vagina, *Expulsion* of the placenta from the uterus, and *Separation with expulsion* of the placenta. *Revision* of the *uterus* means the examination of the uterine cavity after delivery of the placenta and the removal of retained products of conception.

A. H. Freeland Barbour[1] in an elaborate paper shows the results obtained in the last few years from a study of frozen sections in their bearing on the mechanism of labor. Twenty-three reports of these sections at or near full term are collected and studied. He concludes that "frozen sections have greatly extended the scope of our investigation of the process of labor beyond what was possible by clinical study, and, while the method has its limitations, the results stand among the most important contributions made during the last half-century to the science of obstetrics. The pelvis lined with soft parts has replaced the bony pelvis in our discussion of the mechanism of labor. The relations of the peritoneum have been defined, and the position and behavior of the bladder made visible. The whole idea of a lower uterine segment has grown up round Braune's section and the subsequent ones. The behavior of the uterine contents in labor has also become a matter of direct observation. The old idea of the fetus as a more or less rigid body has been displaced by one that emphasizes the plasticity of the fetal mass, the nonrigidity of the spine, and the mobility of the head on the shoulders. The retrogressive changes in the puerperium, in so far as these affect the bulk of the uterus, and the height of the fundus and the length of the canal have been made the subject of exact measurement." [These studies afford an explanation of the well-known clinical fact that patients do not bleed until the third stage has begun. If the old view were correct that separation takes place during the second stage, there should be bleeding during that stage, but there is none. They also give us a *rationale* of the arrest of hemorrhage. The vessels are ligatured by muscular retraction before the placenta is amputated. The third stage to a certain extent resembles the second, the uterus now operating on the placenta as it formerly did on the fetus.] Nichols[2] suggests a new and rational method of delivering the placenta by "axis-adjustment;" that is, he makes the axis of the doubled-up placenta —that passing through the points of reduplication of its edges, these points corresponding to the poles of the fetus—correspond to the axis of the uterus —that line passing from the center of the os to the center of the fundus. If the axes correspond, placental delivery is easy; if they do not correspond, the placenta is retained *in utero*, and this he terms "*placental cross-birth.*" In such a case he corrects the position of the structure by an operation which he terms *placental version*, the latter being accomplished by three methods—external, internal, and combined or bipolar, the external method being the preferable one.

Stubbs[3] records the case of a patient who in August, 1895, complained that her menstrual flow was 6 weeks overdue. She suffered from pain, faintness, nausea, and slight vaginal flow. Pelvic examination showed an enlargement of the left Fallopian tube and cornu. In November the tubal mass was markedly larger and the uterus considerably increased in size. The patient then visited another physician, who introduced a sound. About 10 days later

[1] Edinb. Med. Jour., Aug., Sept., Oct., 1895. [2] Med. Rec., Aug. 17, 1895.
[3] M. and S. Rep., Feb. 15, 1896.

the labor began, and after 4 days the fetus was expelled. Vaginal examination now showed a mass still present in the tube and cornu, although smaller than at the first examination. After waiting 8 days for the placenta to be expelled spontaneously, it was removed by the fingers and curet from a curious constricted opening on the left side of the uterus. [It is probable that this was a case of implantation of the placenta in the rudimentary horn of a bicornuate uterus, rather than in the lumen of the tube itself, as the author was inclined to believe.]

A New Method of Ligating the Umbilical Cord.—Budin[1] has devised a new method of ligating the umbilical cord with strong linen thread, as follows: The cord is first tied by encircling it with the ligature and tying firmly in a surgeon's knot; one portion of the ligature is then passed half round the cord, and the two strands are again tied perpendicularly to the first, the knot being brought down upon the cut end of the cord about at its middle. This results in the separate ligature of one-half of the cord containing the umbilical vein and one of the arteries. The ligature is then passed in a similar way about the other umbilical vessel, and the knot again tied in the middle of the cut end.

Treatment of the Puerperant.—Barker[2] suggests that the puerperal woman is injured by being maintained for too long a period in the recumbent posture. He thinks that after the fourth day she should be allowed to assume the semi-recumbent posture. When there have been produced minor injuries (contusions) of the external genitalia he[3] employs the hot medicated pack (hot water, to a pint of which are added 2 ounces of the fluid extract of witch-hazel, a napkin being saturated in this and applied to the parts). This may be changed every 15 minutes for the first 3 hours, and afterward every ½ hour to 1 hour for 6 hours. To hasten involution Gill Wylie[4] recommends the use of boroglycerid pledgets in the vagina.

Involution and its Anomalies.—C. K. Broers[5] in his inaugural thesis at the University of Leyden considered the subject of puerperal involution of the uterine muscles, basing his conclusions on careful study of the rabbit at various parts of the postpartum period. He expressed the opinion that at the beginning of the puerperium the diminution in size of the uterine muscle is to be attributed to a glycogenic effusion of the hypertrophied muscular fibers, with a resorption of the edematous intermuscular fibrous tissue. Probably the glycogen, having undergone a chemical modification, is transported by the lymphatics. This effusion of glycogen, which begins in the first hours after delivery, is the sole factor in the diminution of the musculature—a diminution which follows a progressive course until the end of the first day, when a new factor is added. Small fat-globules collect in the muscular cells, and little by little increase in size and become confluent. They leave the cells and are temporarily deposited in the inter-

[1] L'Obstétrique, 1896, No. 1.
[2] N. Y. Med. Jour., July 6, 1895.

[4] Med. Rec., Sept. 4, 1895.
[5] Univ. Med. Jour., Oct., 1895.

muscular fibers, to be finally expelled on the fifth day. Their expulsion causes a considerable decrease in the size of the muscles, which by the end of a week and a half have reached the average normal dimensions. The process in no way implies a destruction of the muscular fiber, the fat which is formed being transported by the lymphatics and vessels so slowly that at the end of nearly 5 weeks it has not entirely disappeared. The same process also goes on in the coats of the arteries, the lumina of which occasionally undergo considerable contraction—so much so that an artery may sometimes be entirely closed from proliferation of its internal coat.

In discussing the atrophic uterus and subinvolution after labor Bossi[1] recognizes 4 varieties of atrophic uteri: 1. A uterus atrophic from arrest of development (*a*) during the embryonal period—*fetal* or *congenitally atrophic;* (*b*) at birth or shortly afterward—*infantile uterus;* (*c*) at about the time of sexual development—*adolescent uterus;* 2. A uterus atrophic from pathologic reduction of its size during sexual life, but before fecundation; 3. A uterus atrophic from pathologic reduction of its size during active sexual life, after one or more pregnancies, but from some cause independent of the last pregnancy or labor; 4. A uterus atrophic from hyperinvolution—that is to say, from a pathologic excessive reduction dating from and related to the last parturition and the last puerperium. He thinks this last variety may be due to an exaggeration of the after-pain. The symptoms noticed are a gradual decrease in the strength of the patient, progressive emaciation, and anemia. The milk becomes lessened in amount and disappears. Amenorrhea and sterility supervene. The circulation is irregular, the digestion poor, the appetite morbid. There is ptyalism. Respiration becomes difficult, sometimes to the point of dyspnea. There are headaches, nervous phenomena connected with the special senses, pains in various parts of the body, especially in the right hypochondrium, the latter symptom being almost pathognomonic of hyperinvolution. There are general weakness and profound melancholy. Locally, it will be noticed that any wound upon the cervix uteri heals with remarkable rapidity. Treatment must consist of hygienic and dietetic measures, with tonics, massage, electricity locally applied, frequent sounding of the uterine cavity, warm vaginal douches, and often measures to irritate and excite the part to the point of hyperemia.

Lactation.—Wiedon[2] has collected interesting statistics at the Freiburg Maternity. Out of 525 women in childbed, only one-half could suckle thoroughly during the first 2 weeks; 99 secreted no milk; 49 had imperfect nipples, 46 fissured nipples, and 44 insufficient secretion of milk. Only 33 suckled without unfavorable complications. Wiedon groups the breasts into 3 classes. According to the percentage of his series, good breasts give 56%; medium, 21%; bad, 11%, of rich milk. The development of the nipple bears a direct relation to the value of the breast as a secretory organ.

Wröplewski[3] has made researches into the comparative properties of casein

[1] Ann. di Ostet. e Gin., Jan., 1896. [2] Univ. Med. Mag., May, 1896.
[3] Centralbl. f. Gynäk., No. 32, 1895.

in woman's and cow's milk. The casein differs in the two kinds of milk. In woman it contains less carbon, nitrogen, and phosphorus, but more hydrogen and sulphur. The solubility of the casein differs, and different chemical changes go on when cow's or woman's casein is submitted to gastric digestion.

Külz [1] has analyzed human milk, and in so doing has taken every precaution to prevent the entrance of air from without before making the analysis. Hoppe-Seyler in 1859 made out the proportions of the most abundant gases, as follows: Oxygen, 0.16%, carbon dioxid, 1.88%, and nitrogen, 1.38%. More recent authorities give conflicting evidence. Setschenow and Pflüger found carbonic acid in much larger proportion (6 or 7%). As the result of careful analysis of 5 samples from 3 women, Külz has arrived at very uniform proportions; in fact, roughly speaking, the gases stand at, oxygen, 1.5%, carbon dioxid, 2.5%, and nitrogen, 3.5%. In all 5 samples the gases kept the same figures as above indicated, with but slight variation in decimals.

Worcester [2] describes work done in Dresden for the purpose of rendering cow's milk as nearly as possible an equivalent for mother's milk. The plan followed is based upon the belief that cow's milk is poor in lactalbumin. White of egg is taken as most closely resembling lactalbumin and being easy to obtain. The white of 1 egg is added to 1 pint of cow's milk and 1½ pints of water. To secure the necessary fat, the milk should contain 9½% of fat, while sugar is added in the form of 13 drams of milk-sugar. Under strict precautions for asepsis the white of egg is thoroughly beaten with the milk-sugar, and the 1½ pints of water slowly added, stirring constantly. This emulsion is then strained through fine linen into sterilized milk. The whole should be slightly stirred or shaken and poured into a nursing-bottle. If strict cleanliness has been observed, this mixture may be kept for days or even months.

Conception during the Puerperium.—Cases of conception occurring during the puerperium are recorded by Gruber [3] and Brasseur.[4] In the latter case the second pregnancy lasted 243 days, or 27 days less than the normal. The child measured 52 cm. in length and weighed 3550 grams.

MATERNAL DYSTOCIA.

Contracted Pelvis.—Klien [5] describes a new method of measuring the dimensions of the pelvis at its outlet which he has successfully employed in the clinic at Munich. The best method of making the measurements hitherto known is that of Breisky: it consists in measuring externally the distance between the tuberosities of the ischia, and also in taking the distance from the junction of the sacrum and coccyx to the lower border of the *ligamentum arcuatum*. While this method is fairly accurate and successful, it does not give all the information desired. With a view of increasing the accuracy of

[3] Der Frauenarzt, July, 1894.
[4] Buffalo Med. Jour., Oct., 1895.
[5] Monatsh. f. Geburtsh. und Gynäk., 1895, Bd. ii. H. 3.

the measurements, Klien has devised an instrument composed of a cross-bar terminating in two disks which are placed upon the tuberosities of the ischia. To the middle of this bar is joined what is essentially a pair of compasses, having a graduated scale fastened across them. With the patient lying upon her back the two disks are pressed firmly upon the skin opposite the tuberosities of the ischia, while the attached calipers or compasses are used to outline a rhomboidal shape extending from the subpubic ligament to the point of the coccyx. The result is a rhomboidal outline, the various dimensions of which can be computed by the formulæ applicable to a rhomboidal figure. Klien utilized this instrument to advantage in measuring the pelvis of a woman who had fallen in childhood, breaking her leg and dislocating her hip. As the patient grew to womanhood the result of this injury was an obliquely contracted pelvis. It was possible by Klien's method to measure accurately the outlet of this pelvis in the manner described.

Flint[1] summarizes the records of 6000 cases of pregnancy in which contraction of the pelvis was noted in 654, or $10\frac{9}{10}\%$. Comparison of the measurements of the head, weight, and length of the child with the measurements of the pelvis gave no definite results. In $86\frac{8}{100}\%$ (563 of the 654) delivery was spontaneous. In all of these cases the contraction was slight, the true conjugate being $3\frac{1}{2}$ to $3\frac{1}{3}$ in. In 91 cases operative interference was necessary. Of 663 children, 31 were stillborn, a total infant mortality of $5\frac{58}{100}\%$. In contractions of this degree forceps or version may be selected. Schatz[2] says that the clinic at Rostock shows 9% of narrow pelves; 3% uniformly narrow; $4\frac{1}{2}\%$ flat (nonrachitic); 1% flat and rachitic. 70% of all cases in flat pelves are delivered without aid. Version yields 75% of living children in simple flat pelves, the best results being obtained if version be performed before the rupture of the membranes and with a dilated os. Compression of the skull is attended with less fatality than very high extraction with difficult arm delivery. Leopold[3] favors the assumption of Walcher's hanging position after the extraction of the arms, and disapproves of version in primiparæ if avoidable. Tscherneffsky[4] gives the statistics of 24 cases of intrauterine version by the feet performed by him since 1890 in cases of narrow pelves. The result was 11 living children, to whom should be added 2 more who were born alive, but could not be resuscitated, 10 stillbirths, and 2 not born alive. The average weight of the children born alive was 3851 grams; the maximum weight, 4700 grams. The after-coming head was perforated in 3 cases. Six of the patients were primiparæ, and the maternal mortality was 1. Tscherneffsky believes that the after-coming head adapts itself better to the conditions of a contracted pelvis than when that part precedes the breech. Ahlfeld[5] believes that a simple flat pelvis is much rarer than is generally believed, many so-called pelves being in reality instances of flat rachitic pelves. Neumann[6] reports a case of kyphosis lumbalis in a woman 26

[1] Med. Rec., 1895, vol. xlviii. No. 17.

years of age, and gives the illustrations (Fig. 104). Klien[1] comes to the following conclusions regarding labor in kyphotic pelves from a study of 95 cases: Kyphotic pelves are found in labor about once in 6016 cases. They are generally developed in childhood from spinal caries. In 8% the spinal column projects over the pelvis. Both inlet and outlet of the pelvis are nar-

FIG. 104.—Kyphosis lumbalis (Wien. med. Woch., Feb. 15, 1896).

rowed from side to side and in the anteroposterior diameter. The inclination of the pelvis is diminished, while the true conjugate is almost always lengthened. The nates are flattened; 30% of all kyphotic pelves are also universally contracted. Three-fourths of the cases terminated by spontaneous labor, one-fourth prematurely. In a third of all head-presentations the position was posterior, and face-presentations were more common than in normal pelves. From 58 to 60% of the cases studied required operative interference. The mortality of the mothers in the cases most favorable for the mechanism of labor was 6.2%, in unfavorable cases 17%. The mortality of the children was about 40%. As regards treatment Klien advises the induction of labor in cases in which the distance between the tuberosities of the ischia measures from $8\frac{1}{4}$ to $6\frac{1}{2}$ cm. If the patient be not seen until the end of preg-

[1] Arch. f. Gynäk., Bd. 50, H. 1, 1895.

nancy, symphysiotomy should be done if the distance between the tuberosities of the ischia measures $5\frac{3}{4}$ cm. If a greater measurement exists, forceps can be tried. Cesarean section is only absolutely indicated when the distance between the tuberosities is less than $5\frac{1}{2}$ cm., and is relatively indicated when the distance is from $5\frac{1}{2}$ to 7 cm., if by it a living child can be obtained and symphysiotomy is undesirable.

Budin [1] gives the diagnosis of the iliofemoral pelvis—that due to congenital dislocation of the hip. The normal distance between the sole of the foot and the articular boundary line of the knee is equal to that separating the latter line from the superior trochanteric region. A line passing the two spines of the os pubis also crosses the epitrochanteric line. In dislocation of the hip the epitrochanteric line lies above the two spines of the os pubis, and may reach the iliac spine; it also lies higher on the sacrum than normally—the junction of the sacrum and coccyx. In discussion Rapin calls attention to a symptom of congenital dislocation often neglected—namely, the approximation of the posterior-inferior iliac spine to the crest of the sacrum on the affected side. Bodo [2] records a case of circular rachitic pelvis associated with double spontaneous posterior luxation of the thighs. Wassilieff [3] reports the delivery of a living child in a woman with contracted pelvis by the employment of the obstetric lever.

Puerperal Eclampsia.—Interesting cases of this complication are recorded as follows: A. D. Price,[4] 1 case, with recovery; Scadding,[5] 2 cases, with recovery; Polak,[6] 9 cases, with 2 deaths; 8 of the women were primiparæ, and in 6 the labor had begun before the convulsion appeared; 3 children were born dead; Harrison,[7] 1 case, with recovery after treatment by veratrum viride and morphin; S. S. Jones,[8] 2 cases, with recovery, treated by veratrum viride; Davis (E. P.),[9] 5 cases, 1 resulting fatally; Williams,[10] 2 cases, 1 resulting fatally; Schreiber,[11] 4 cases, 1 perishing; he employed in treatment the hot pack, inhalations of chloroform, and morphin injections; Robert,[12] 1 case, recovering after forced delivery by the hand; York,[13] 1 case, occurring in a primipara 8 hours after a natural labor; a cure followed the use of veratrum viride; Freeman,[14] 1 case, with recovery; Mackness,[15] 1 case, with recovery; J. S. Davis,[16] 1 case, treated successfully with large doses of tincture of veratrum viride; and Craik,[17] 2 cases, both recovering under pilocarpin treatment. T. K. Holmes,[18] reports a series of 47 cases with 19 maternal and 20 fetal deaths; labor was induced 9 times, with no death either to mother or child; he believes that

prophylaxis is most important, and that a diminution in the quantity of urine, the presence of albumin or of a low specific gravity, demands prompt recognition, and, if associated with nervous disturbances, pain, or anasarca, means imminent danger. S. C. Red,[1] in an experience of 9 cases with 2 deaths, classifies his cases as symptomatic, reflex, and toxic. He endeavors to treat the symptom, to remove the peripheral irritation, and to relieve the toxemia. An interesting case of eclampsia in both mother and child is reported from Schauta's Clinic in Vienna by Woyer.[2] The patient was a primipara, and was admitted to the hospital partially comatose and suffering from eclamptic convulsions. Labor was hastened by an elastic dilator, and the child delivered by version; it was asphyxiated, but was resuscitated. The mother made a gradual recovery, and left the hospital 2 weeks afterward. Five hours after birth the child was taken with eclampsia, accompanied by tracheal rales and impaired respiration. The pulse rose to 144. In all, the child had four convulsions at intervals of an hour or two, and died cyanotic with heart-failure after the fourth. The postmortem examination showed acute edema of the lungs as the only lesion present. Bacteriologic examination of the various organs and examination of the urine found in the child's bladder gave negative results. [The few cases of infantile eclampsia on record have ended fatally.] Dohrn[3] reports a very interesting case of a patient in fatal eclampsia in whom the os and cervix were so tightly closed that artificial dilatation was impossible; accordingly, Cesarean section was practised immediately after death. It was found that the fetus had perished, and apparently in a convulsion, as the jaws were tightly closed, the arms and legs bent, and the fingers drawn strongly into the palms. So rigid were the muscles that it was necessary to open the uterus widely in order to extract the child; this persisted for 16 hours after the delivery of the fetus. Postmortem examination of the child showed extravasation of blood beneath the dura and in the arachnoid spaces over the left cerebral hemisphere. Rabczewsky[4] has observed an instance of convulsions during pregnancy in which every fit was regularly preceded by transitory amaurosis, as well as by edema of the face, which was also of short duration. [Olshausen has been able to collect only 3 cases of eclampsia in which the fit was preceded by an aura, as in this case.] Abelin[5] records a case of eclampsia, with subsequent tetanus due to biting of the tongue, developing on the eighth day after delivery and terminating fatally 2 days later. [Tetanus following labor or abortion is exceedingly rare, although Venay has collected 106 such cases.] Zweifel[6] reports his experience of 129 cases of puerperal eclampsia treated in the Leipzig Clinic, and contrasts those treated by the expectant method (before 1892) with those treated actively by Dührssen's plan of emptying the uterus as soon as possible: 49 cases were treated by the former method, with a mortality of 32.6 %;

[6] Centralbl. f. Gynäk., Nos. 46, 47, and 48, 1895.

80 by the latter method, with a mortality of 15%. After a careful study of the 129 cases, Zweifel concludes by advocating the principle of immediate delivery by operation in every case of eclampsia, by dilatation with elastic bags, and, when the cervix is already taken up, slight incisions into the os or, in cases not so far advanced, by making extensive incisions into the cervix. As the amount of blood that may be lost after these incisions cannot be estimated, venesection, which is very useful when the fits persist after the child is born, especially when the pulse is of high tension, is, unless under the same condition of the pulse, hardly advisable before delivery, although the older authorities are agreed as to the surprising effect it has in accelerating dilatation. While nothing should be given to an unconscious patient to swallow, a proper sound may be used to introduce liquid nourishment, to siphon out the stomach when desirable, or to administer weak solutions of acetic, tartaric, or citric acid, which in extreme restlessness are most beneficial. Zweifel does not consider ether contraindicated as an anesthetic. Either this or chloroform may be employed. Finally, he insists that a rigid asepsis is the more necessary, as infection favors the recurrence of the fits. [These results are especially interesting in view of a change in belief that has gradually come about in the minds of many obstetricians. Dührssen's method of incising the neck of the uterus makes delivery possible in those cases in which the pelvis is not contracted or the child not excessive in size. As has been suggested, it is safe to say that within the past year American obstetricians seeing the largest number of cases and operating most frequently have come to share the conclusion expressed by Zweifel.] Polak [1] also employs this method.

Cassaet and Chambrellent [2] have made a histologic examination of the kidneys and spleens of stillborn infants of eclamptics and of children born of eclamptics who died soon after birth. Death was found to be due to two very different causes: 1. To hemorrhagic and degenerative lesions of the placenta; in these cases the fetus died *in utero* and was often macerated at birth; 2. To histologic alterations of the spleen and kidneys resembling the lesions found in the organs of the mother. These lesions explain the great mortality in the infants of eclamptics, even when they are born living and well developed.

Boyd [3] reviews the theories of the causation of eclampsia, and emphasizes the facts that it is not common in women the subjects of chronic kidney-disease before pregnancy; that when kidney-symptoms are present they usually develop suddenly; that kidney-lesions may be absent; that albuminuria is in many cases the effect and not the cause; that it must be remembered that the kidneys are not the only excretory organs whose failure to perform elimination properly may produce eclampsia; and that ptomain-poisoning should not be forgotten. Ludwig and Savor [4] report the results of their investigations concerning the toxicity of the urine and the blood-serum of eclamptic patients.

[1] Loc. cit.

[2] Rev. des Mal. des Femmes, Oct. 25, 1895.

[3] Bull. méd. du Nord, Nov. 12, 1895.

[4] Monatsh. f. Geburtsh. u. Gynäk., 1895, Bd. i. H. 5.

They observed by experiments upon animals that the toxicity of the urine in these patients varies greatly from time to time. Contrary to what might be expected, during the convulsions the toxicity of the urine is much less than at other times, while, on the contrary, the poisonous properties of the blood-serum of these cases increases markedly during the time of the convulsions. These results were obtained by injecting into animals the urine and blood-serum from eclamptic cases. Massin[1] is convinced that in the body of the pregnant patient, and especially at the end of pregnancy, there exists an abundance of but partially oxidized products, which he terms "leukomains." These are ordinarily broken up and excreted by the liver and kidneys, but in cases in which these organs are at fault these products may remain within the body of the patient. Their immediate absorption and the effect which they produce depend considerably upon the condition of the nervous system. Whatever increases the sensitiveness and irritability of the nervous system favors the absorption of this material, which is capable of producing eclamptic convulsions when in considerable amount. Williams[2] does not believe that renal disease is the sole cause of puerperal eclampsia. The points that sustain this opinion in his mind are that convulsions may occur in the absence of albumin in the urine; that in many fatal cases of eclamptic convulsions disease of the kidneys is absent or insignificant; and that puerperal convulsions are comparatively rare in persons the subjects of chronic Bright's disease prior to the occurrence of pregnancy. S. Seabury Jones[3] concludes that one is justified in believing that puerperal eclampsia is due mainly to the non-elimination from the system of the pregnant woman of toxins which are the direct and natural product of the physiologic processes incident to her condition, or to the conversion into toxins of such products and their nonelimination, and that the nervous tension of the pregnant woman predisposes to the disease; that while albuminuria during pregnancy should lead to grave apprehension, yet many women who present this symptom escape convulsions (about 7 out of 8), while convulsions may be met with in women whose urine has remained free from albumin until their onset; that he who saves 4 out of 5 women who have been attacked by eclampsia before or during labor may consider that he has been fairly successful; that we have medicines powerful for good, and that they should be given a fair trial before resorting to accouchement forcé in actual convulsions; that at a period when the fetus is viable, especially at the end of the eighth month, if the patient suffer from severe premonitory symptoms, such as anasarca, severe and persistent headache, and the eye-symptoms, and particularly if the evidences of nephritis have persisted for some time in spite of treatment, premature labor should be induced in the interest of both mother and child; that in the actual presence of convulsions we should endeavor to overcome them by the use of proper medicines and remedial measures, notably by the use of veratrum viride, morphin, chloral, and chloroform, rather than appeal to the rapid emptying of the uterus; that in veratrum viride we have a powerful remedy for good when properly used,

[1] Centralbl. f. Gynäk., No. 42, 1895. [2] Loc. cit. [3] Med. Rec., Apr. 25, 1896.

but that of Norwood's tincture it is better not to inject more than 5 to 10 minims for the initial dose, to be followed by doses of 5 minims at intervals as required to hold the pulse, and that it is well to combine it with morphin. Manton[1] has collected 8868 cases of delivery, in which number eclampsia is noted as having occurred 33 times; in not a single instance is it stated that *insanity* followed the convulsive attacks. He concludes, therefore, that insanity as a sequel to puerperal convulsions is of such exceedingly rare occurrence as hardly to deserve consideration in this connection.

[In the *treatment of eclampsia* veratrum viride still holds the place it has recently gained in the estimation of obstetricians, and the results of increasing experience give promise that it will meet the fondest expectations of the most enthusiastic.] Willis[2] reports 2 cases successfully treated by the drug, and others report repeated happy terminations under its use. Tweedy[3] does not believe that a more fatal drug could be found for uremic patients than pilocarpin, while Grinberg[4] has employed the drug successfully in 3 cases, and with fatal pulmonary edema in one case. He believes it is contraindicated in all cases complicated by pulmonary edema. Venous injections of from 1 to 2 pints of normal saline solution are recommended by Lanphear[5] and Audebert.[6] Lanphear claims that these injections dilute the toxins and increase arterial tension to such an extent as to restore the secretion of urine. In very few instances is a third injection necessary. Audebert has also employed the injections after severe hemorrhages during or after delivery or abortion; in cases of autointoxication of variable form, origin, and gravity, and of different symptoms (vomiting, nephritis), with satisfactory results; and in newborn infants, premature, feeble, or with athrepsia. He injects from 300 to 1000 ccm. in adults and from 10 to 30 ccm. in infants, selecting the flanks or the rectotrochanteric groove, and makes use of a glass apparatus with atmospheric pressure. De Goubarew,[7] professor of obstetrics and gynecology in the medical faculty of Dorpat-Yurieff, has found that in cases of eclampsia in women the application to the lumbar region of a large rubber bag filled with hot water produces excellent results. Under this treatment diuresis rapidly increases, while the albuminuria decreases, and general improvement sets in, which is soon followed by recovery. Prof. de Goubarew has had occasion to use this method of treatment in 6 patients suffering from eclampsia, all of whom recovered. The accessory measures employed in these cases were hypodermic injections of morphin, chloral enemata, warm moist wraps, rubbing with a mixture of salt, vinegar, and alcohol, purgatives, and, lastly, milk in abundance. Dührssen's method of deep incision of the cervix to facilitate delivery is growing in favor, and is presenting brilliant results in the hands of many observers, including Edgar[8] of New York. Tweedy[9] believes that chloroform,

[9] Loc. cit.

chloral, and potassium bromid, being powerful cardiac depressants, tend to kill in the same way as eclampsia; he says that chloroform, given when a fit is approaching, has but slight effect in lessening its severity, and by limiting the amount of oxygen reaching the lungs may actually increase this. He does not consider severe diaphoresis justifiable, as it is not always easy to accomplish, not certain in good effects, nor even safe. Pilocarpin he considers as fatal a drug for uremic patients as any, depressing the heart and increasing the saliva and bronchial secretion. Temporary good may follow its use. Drugs, stimulants, and food should not be given by the mouth. Swallowing being impossible, croton oil or saliva enters the lungs more easily than the stomach, and he considers the so-called edema of the lungs in fatal cases to be due to fluids reaching them in this way. For this reason the patient, as in anesthesia, should not be allowed to lie upon her back. The gag, by keeping the lips and teeth apart, prevents swallowing, increasing this danger. The induction of premature labor as a prophylactic is absolutely unjustifiable, as no one can say whether a case will develop eclampsia; less than 6% showing premonitory symptoms do so. He believes that induction of labor adds to the danger, because convulsions are brought on by any reflex stimulation. He advises hypodermic injections of morphin, beginning with $\frac{1}{2}$ gr., followed in 2 hours by $\frac{1}{4}$ gr., and so on until the symptoms are alleviated or 2 gr. have been given in 24 hours. If labor begin, it is hastened by forceps when the os has dilated naturally. Opium has little action on the heart or kidneys: by lessening metabolic changes it limits toxin-formation, diminishes reflexes and salivary and bronchial secretions, counteracting to a great extent the conditions that tend to kill in eclampsia. He also advocates bloodletting to relieve the kidneys, diminish bronchial and salivary secretion, diminish venous congestion, and remove toxins from the body. Stimulants or medicines should be given through a nose-tube or per rectum. Purgatives are essential; the nitrites or digitalis with spartein may be useful.

Rigidity of the Soft Parts.—Instances of *cervical dystocia*—rigidity (either spasmodic or pathologic), edematous elongation, hypertrophy, prolapse of the anterior cervical lips, thrombus of the cervix, and agglutination of the lips—have been reported as follows: Eustache,[1] a case of agglutination of the external os in a primipara of 18 years; Osmont and Chottard,[2] a case of cervical rigidity with shoulder-presentation in a woman of 32 years in her second labor; under traction the fetus was decapitated, and the woman died of sepsis on the twelfth day, after expelling spontaneously the fetal skull; Charles,[3] a case of cervical rigidity in a primipara of 19 years, with maceration of the fetus; Geyl,[4] a case of edema and prolapse of the cervix; Swift,[5] 3 cases of the same condition; Wells,[6] a case of cervical hypertrophy; T. C. Smith,[7] a

[7] Ibid., Jan., 1896.

similar case in a primipara of 22 years, the hypertrophied infravaginal cervix protruding from the vulva at least 2 inches; and Weisenberg,[1] another case of the same condition. The etiology of obliteration of the os is obscure, among the many causes mentioned being stenosis prior to pregnancy from metritis, granulation and cicatrization of simple inflammatory, diphtheric, gangrenous, syphilitic, or traumatic origin, and the formation during pregnancy of a plastic plug or of a caducous membrane. Depaul distinguishes between obliteration of the internal and external os uteri, the latter being the most frequent. Weagly[2] recommends the following anesthetic solution for cervical rigidity: Phenolized cocain solution (3%), f℥j; trinitrin solution (2%), ♏x; strychnin sulphate, gr. $\frac{1}{6}$; listerin, f℥j; this is sprayed upon the parts. Farrar[3] has also employed cocain (10% solution) to dilate the cervix, with gratifying success. [This employment of cocain requires further confirmation before its general adoption is recommended; the danger of cocain-poisoning and of sepsis must be borne in mind.] Instances of pregnancy associated with an unruptured hymen are recorded by Braun;[4] Guerard,[5] 3 cases, 1 having a bifenestrated hymen in which the openings barely admitted a hair; and Mayer.[6] Brindeau[7] calls attention to the fact that delayed delivery in primiparæ is not due so much to rigidity of the perineum as to rigidity of the vaginal orifice. It is not uncommon to see the vulvar ring remain absolutely intact after labor, while, on the other hand, the vaginal orifice is always torn at the moment that the head is expelled. These facts were pointed out long ago by Matthews Duncan and Budin, and render it easy to understand how, if the tissues at the vaginal orifice of a primipara are unduly rigid, spontaneous delivery becomes impossible. In 2 cases reported by Brindeau the vulvar orifice was elastic, but the birth of the head was prevented by the rigid tissues surrounding the vaginal orifice. In both the tough ring of tissue was incised with scissors, and almost immediately after this the head was expelled spontaneously. The incision commenced in the middle line, and was made to extend obliquely upward for about $\frac{1}{2}$ in. After delivery it was closed with sutures.

Perineal Laceration.—Von Woerz[8] gives the notes on the injuries of the maternal perineum observed in Schauta's Clinic during the years 1892–94: Of 8495 labors, 734 resulted in perineal injuries = 8.7%. Of these, 313 = 3.68% were episiotomies, and 421 = 4.96 were lacerations. Out of 3832 primiparæ, 643 suffered injuries (16.51%); of 4663 multiparæ, only 91 (1.92%). With children of 1500–2500 gms. weight there were in 716 births 39 injuries = 5.44%; of 2501–3000 gms. in 2733 births 226 = 8.27%; of more than 3000 gms. in 5046 births 469 injuries = 9.29%. In the institution 8103 births were spontaneous with 574 injuries = 7.08%; among 3613 prim-

iparæ with spontaneous birth 498 injuries = 13.78%; and 4490 multiparæ with 76 injuries = 1.69%. Of 364 breech presentations, 51 had tears = 14% (123 primiparæ with 31.7%, 241 multiparæ with 4.97%). The great importance of forceps operations as regards perineal lacerations is shown by the fact that in 227 forceps cases 145 injuries occurred (63.87%); of 179 primiparæ 137 suffered; of 48 multiparæ, 8 had injuries—a percentage, respectively, of 75.53 and 16.66. Von Woerz concludes that the frequency of perineal lacerations during labor increases with the weight of the children born, and occurs more frequently when the perineum is not supported. Flesch[1] reports 2 unusual lacerations of the perineum. One patient was a young woman aged 19 years, who sustained an injury to the perineum consisting of a central laceration which left the posterior vaginal wall at its lower portion intact, but tore the tissues between the bowel and the vagina, the head being born apparently through the anus; the sphincter ani was entirely torn apart. The second case was one in which a resisting hymen was torn in an annular manner, being entirely separated from the surrounding tissue. In the repair of perineal lacerations Dickinson[2] employs a Hagedorn needle fixed to a Peaslee shank, as shown in the accompanying illustration (Fig. 105); with

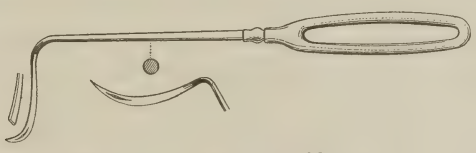

Fig. 105.—Dickinson's perineal needle (Brooklyn Med. Jour., May, 1896).

this instrument the point of the needle is readily found in the tissues and the operation facilitated.

Tumors.—Shearer[3] records a labor obstructed by an overdistended bladder containing 2 quarts of urine. Chambrelent[4] relates a case in which a bony tumor of the pelvis necessitated pelviotripsy in a woman who 2 years before had passed through a perfectly normal labor; and Lees[5] records a case of sarcoma of the sacrum necessitating Cesarean section; the patient died in 4 hours' time.

Mann[6] contributes an interesting and important paper on the sloughing of uterine fibroids after abortion and labor. While it is true that in some cases of pregnancy complicated by fibroid tumors labor proceeds without any difficulty, this is by no means the general rule. Stavely has collected the records of 597 cases in which nothing was done until labor came on. Of these, 220 died—a mortality of 37%. In 548 cases collected by the same writer 15% aborted, and in 307 of those in which the maternal mortality was noted there was 12% of deaths. This would certainly show that in cases in which there is no interference the mortality is simply frightful, and would warrant the general statement that interference is usually justified. The percentage of

[6] Am. Gynæc. and Obst. Jour., Apr., 1896.

deaths where abortion occurred is so much lower than where the labor went to term that the advisability of inducing abortion would seem also to be shown. The danger after abortion, as has been proved by the records of many cases, comes principally from distortion of the uterine canal, making it impossible to entirely clear out the placenta and membranes. Small portions, being left, decompose and set up sepsis. An additional source of the sepsis is the sloughing that frequently occurs in the fibroid growths from the devitalization that follows the pressure to which the tumor has been subjected. The low vitality of these growths makes them peculiarly liable to septic invasion. Mann concludes, therefore, that should sepsis occur in a uterus after labor or after an abortion, such a uterus containing fibroids of any amount or size, unless the symptoms subside very promptly under douching and curetting, an operation for the removal either of the tumor or of the uterus and tumor should be undertaken at once.

Labor after Suspensio Uteri.—[Sufficient time has now elapsed to determine the effects of ventrofixation of the uterus upon subsequent pregnancies. The experience of observers is now very general that the operation is not so free from subsequent complications as was formerly supposed.] Graefe[1] records 2 cases in which uterine rupture was threatened, both patients being delivered by Cesarean section; in 1 case the right broad ligament had ruptured and the patient perished from hemorrhage. Goubaroff[2] records a case of labor with transverse presentation in which the uterus was very firmly adherent to the anterior abdominal wall; Cesarean section was required to prevent uterine rupture. Norris[3] records a case in which the anterior uterine wall throughout its entire length was fixed to the abdominal wall; the posterior uterine wall was so dangerously thin that delivery by the forceps was required, a dead fetus being extracted. Velde[4] records a case in which the anterior vaginal fornix was drawn up very high, the uterus sharply anteflexed, the cervix displaced to the right, the child transverse, and the uterus so contracted that version was impossible; a Porro-Cesarean section was performed, and the uterus found to be ruptured; both mother and child died. In another case a successful Cesarean section was done. Miländer[5] adds 2 cases, in 1 of which there was retention of the placenta, and in the other version was required. Among 207 cases of vaginal fixation operated upon by Dührssen,[6] 20 have had children; of these 3, or 15%, had difficult labor.

One of the most interesting and important contributions to this subject is the paper by Strassmann.[7] He writes from the Polyclinic of the Charité in Berlin. Three methods of suspending the uterus by operative procedure are recognized: one in which the uterus is suspended by shortening the round

[1] Monatsh. f. Geburtsh. u. Gynäk., 1895, Bd. ii. H. 6. [2] Arch. de Tocol., No. 11, 1895.

ligaments, a second by joining the uterus to the anterior wall of the abdomen, and the third by uniting the womb to the bladder or to the anterior wall of the vagina. So far as the results of pregnancy go in cases operated upon by these different methods, shortening the round ligaments would seem to give the best results, with the least interference with the natural mobility of the uterus during pregnancy and labor. The number of abortions occurring in these patients is also very small, and no case is found upon record in which at labor serious complications have arisen. Pregnancy seems to occur as frequently as is normal after this operation. Of the various methods of suspending the uterus to the anterior wall of the abdomen, that of Czerny and Leopold seems best, because by this method the stitches are removed and the uterus is left more mobile than in cases in which the sutures are retained. Pregnancy frequently occurs after this operation, and the number of abortions is not noticeably great. Strassmann reports the case of a multipara, aged 36 years, whose uterus had been suspended to the abdominal wound with catgut sutures in an abdominal section by which an ovarian cyst upon one side had been removed. When labor came on, the tissues at the site of the original scar were very much drawn in, while the descent of the child seemed hindered by the lack of mobility in the uterus. Not much difficulty was experienced in extracting a living child with forceps. Free hemorrhage occurred after the delivery of the child, which was only checked by carrying the uterus strongly downward into the brim of the pelvis and by placing a compress above the uterus with an abdominal binder. It was observed in this case that the adhesion between the uterus and the abdominal wall stretched readily, and that the fundus and posterior wall of the uterus were also adherent. It was observed that adhesions between serous surfaces permitted the greatest elasticity during labor and gave the best results in delivery. When, however, the uterus is attached to the wall of the vagina, the adhesion is by connective tissue and a firm and unelastic scar develops. Unless the posterior wall of the uterus distend greatly during pregnancy, abortion is inevitable. Dührssen finds that in cases becoming pregnant after this operation 25% aborted. Of patients treated for retrodisplacements with pessaries but $16\frac{6}{10}\%$ aborted, while of patients treated by fixation of the uterus to the vagina $27\frac{2}{10}\%$ aborted. If retroversion of the uterus be compared with other diseases of the uterus, it is found that retroversion offers the least obstacle to conception. It is possible for the uterus to become separated from the vagina during pregnancy. If it does not, the uterus must become greatly distended in its posterior wall.

Strassmann describes 2 cases of labor in patients in whom the uterus had been attached to the anterior wall of the vagina. In the first case the cord prolapsed, the mouth of the womb was drawn upward and backward, while the anterior wall of the vagina was forced downward and very greatly distended. In this sac lay the right shoulder and arm. A difficult version made possible the delivery of the child, followed by severe hemorrhage. In this case, as retraction of the uterus did not take place, it was necessary to carry

it down into the pelvis and to retain it there by a pad and bandage. The patient made a good recovery. The second case reported is that of a patient from whose uterus a small fibroid had been removed, and the womb attached to the anterior wall of the vagina. At labor it was found that it was very difficult to empty the bladder; the mouth of the womb was drawn very strongly upward and backward, the child being in shoulder presentation. Although dilatation was advanced by elastic dilators, it was impossible to make version because of the danger of rupturing the uterus. An eclamptic attack supervened and tetanus of the uterus gradually developed. The anterior vaginal wall formed a sac or pocket, and the posterior wall and posterior portion of the lower uterine segment were greatly distended. Under anesthesia it was found impossible to perform version or craniotomy. Abdominal section was accordingly done, the uterus amputated, and the stump fastened to the abdominal wound. The patient died of shock. On postmortem examination a laceration of the vagina was found between the anterior lip of the uterus and the point of fixation of the fundus. Some hemorrhage had occurred from the region of the right broad ligament into the abdominal cavity.

In view of the complications arising at labor Strassmann would limit suspension of the uterus to Alexander's operation or to a ventrosuspension by bringing together serous surfaces and removing the stitches. In view of the fact that many cases can be cured by pessaries and other methods of treatment, he would avoid, if possible, suspension of the uterus in women who are likely to bear children.

Dystocia following Vaginofixation.—Among the many recent contributions to the literature of this subject is that of Wertheim.[1] He found that out of 37 cases of vaginal fixation of the uterus, 3 had subsequently become pregnant. One of these terminated in abortion at 4 months, another in normal labor after a normal pregnancy. The third patient was one in whom the tissue between the bladder and the uterus had been opened and the uterus had been directly united with the vagina. Before the pregnancy the fixation of the uterus was a remarkably firm one. As pregnancy progressed the vagina was drawn up with the growing uterus, forming a diamond-shaped area, accompanied by the gradual ascent of the vaginal portion of the cervix. Fearing complicated labor, the patient was instructed to enter the clinic upon the onset of labor. Upon examination, the fetus was found in a transverse position, the head upon the right side, the fetal heart-sounds near the umbilicus. The anterior wall of the vagina was drawn up behind the symphysis, so that the scar could scarcely be felt. The cervix was so high that it was necessary to introduce the entire hand to reach it. The anterior lip of the cervix was thickened, the posterior lip very much thinned. But little of the uterus remained within the pelvis. The round ligaments on both sides could plainly be felt converging toward the middle line at the region of the umbilicus. The patient was a multipara, and had strong labor-pains, in spite of which the birth did not advance. The

[1] Centralbl. f. Gynäk., 1896, No. 2.

cervix dilated very slowly, the anterior wall of the uterus being drawn down above the symphysis. It was necessary to hasten labor on account of the great distention of the posterior wall of the uterus, which threatened rupture. Under deep anesthesia combined version was performed and a foot drawn down. Three hours afterward a living child was delivered. Immediately after labor the uterus was examined by the hand; the thinning of the posterior wall of the womb was very remarkable, and the vagina seemed to pass into the uterus without appreciable distinction. The patient made an uninterrupted recovery. On examination afterward the attachment of the uterus to the anterior vaginal wall was found in no way weakened.

Rühl[1] thinks that the difficulties attending parturition after vaginofixation have been exaggerated. He has performed vaginofixation 235 (*sic*) times, and is well satisfied with the results. He had the opportunity to observe 10 cases that subsequently became pregnant and were delivered at term. Of this number 7 were delivered naturally and 3 by podalic version, with favorable results to mothers and children. The chief obstacle to delivery, in Rühl's opinion, is the tense, hard anterior lip of the cervix, which is prevented from dilating. Delivery can be made easy by incising the ring that is formed by this unyielding tissue. [These results differ widely from the majority.]

Rupture of the Uterus.—Fatal cases are recorded by Doléris and Bonnus,[2] Tighe,[3] Baldwin,[4] Wilkinson,[5] Townsend,[6] Albers-Schönberg,[7] Marx,[8] 2 cases, and Cecil,[9] a case of separation of the vaginal attachment to the uterus with expulsion of the fetus into the abdominal cavity. Recoveries after uterine rupture are recorded by Reusing,[10] Quesnier,[11] Fenner,[12] and Cholmogoroff.[13]

Sänger[14] at the Sixth Congress of German Gynecologists at Vienna proposed a classification for rupture of the uterus. In his first group he places simple rupture, complicated rupture, multiple rupture, fissures, bruising (by pressure), and rupture caused by the presence of neoplasms. The second group comprises ruptures produced during pregnancy, those produced after delivery, and postmortem rupture (a case of Zweifel's). In the third group are placed spontaneous ruptures (that is, those due to anomalous delivery), ruptures produced by operative interference or some traumatism from within, and ruptures caused by external traumatism. A small group includes ectopic pregnancy (tubouterine pregnancy, pregnancy in one horn of a bicornate uterus). He believes that all possible ruptures can be included in these groups. The predisposing causes of rupture of the uterus are as follows: 1. *Acquired predisposing causes:* Cicatrices due to old tears or Cesarean section; thinning out of the cervix; thinning or atrophy limited to the muscle of the uterus; atrophy of the entire uterus (tuberculosis, morphin habit, Basedow's disease),

atresia of the cervix, placenta prævia. 2. *Predisposing congenital causes:* Thinning of a part of the wall of the uterus (uterus arcuatus, incudiformis, unicornis, and bicornis), and in atrophy of the entire uterus and vagina (infantile uterus). 3. *Abnormal weakness of the wall of the uterus,* due to a pathologic condition of the tissues. This condition can be caused by septic infection before or during labor, hemorrhagic infarctions, chronic interstitial metritis, tuberculosis, syphilis, myomata, carcinomata. 4. *Abnormal weakness of the tissue,* due to a degeneration of the muscular tissue. This includes both fatty and hyaline degeneration. Passing to the mechanism of rupture of the uterus, we find it very simple after Bandl has made us familiar with it. Rupture is produced if there is a disproportion in the three factors—the genital canal, the expelling force, and the object to be expelled. It takes place when the genital canal is impassable at its lower end, and is due to the drawing up of the muscular fibers and both active and passive hyperdistention and thinning of the median segment of the uterus. The primary causes of rupture of the uterus may be given as uterine contractions and internal and external traumatism. The secondary causes are—(1) Obstructions in the bony pelvis; (2) obstructions in the soft parts, rigidity of the cervix, bicornate uterus, stenosis of the cervix or vagina, malposition of the uterus, and abnormal contractions of the uterus; (3) abnormal resistance of the membranes, abnormal positions or presentations, anomalies of labor.

[The old method of treating a ruptured uterus was purely expectant, but the good results recently obtained from operative procedures have brought them into general use. The two procedures mostly employed are—drainage through the vagina and suture of the uterus after abdominal section.] Fritsch [1] states that Krouer's statistics show that the afebrile (aseptic) cases do well with any treatment or no treatment, while the septic cases do badly whatever treatment is adopted. When a rupture of the uterus is seen 5 or 6 hours postpartum danger of hemorrhage is over, and a conservative course of treatment is best. The peritoneal cavity should not be washed out unless sepsis is present. Hysterectomy for this condition should never be practised, except in cases in which the uterus is septic or contains one or more fibroids.

Inversion of the Uterus.—Cases of this rare accident are reported as follows: Hirst,[2] 3 cases in 10 years' time; Matheson,[3] 1 case, followed by severe hemorrhage; J. H. Morgan,[4] 1 case of complete inversion of the uterus due to traction in the removal of the placenta; Beckmann,[5] 1 case of complete inversion in a primipara of 23 years after a rapid spontaneous delivery; Crouse,[6] 1 case; Himmelsbach,[7] a case of chronic inversion of some years' duration; W. H. Skene,[8] a case of chronic inversion of 7 months' standing which had resisted all efforts at reduction by the ordinary methods, but was cured by Thomas's operation, which consists in opening the abdomen, dilating

the cervix from above, and pushing up the uterus by a hand in the vagina; A. A. Davis and C. W. Packard,[1] a case of 5 days' standing successfully treated, although the patient died within the month of pelvic peritonitis and metritis; Anst-Lawrence,[2] a case of 3 months' duration reduced by means of a repositor; Herman,[3] a case of chronic inversion, in which the treatment by Aveling's repositor was effectual, but produced a limited slough of the uterus; the organ was subsequently reduced. Herman remarks that there are two important points to bear in mind when applying continuous elastic pressure for inversion: the pressure must act in the line of the axis of the inverted uterus, and likewise of the axis of the pelvic brim, and there must be effective counterpressure. Again, the pressure must be carefully regulated, and the apparatus replaced in position as often as the restlessness of the patient makes it necessary. If these precautions are taken, the inversion will usually be reduced in a few days. Fullerton[4] records 2 cases of chronic inversion—in 1, a woman 67 years of age, the inversion being associated with a procidentia uteri, necessitating a complete extirpation of the organ. Verchère,[5] when all means have failed to reduce an inverted uterus, is of the opinion that it is best to perform vaginal hysterectomy. Muzio Pazzi,[6] in a study of this accident concludes: 1. That there is nothing new to add in the way of classification, diagnosis, prognosis, course, or treatment of recent puerperal inversion. 2. In regard to the pathologic anatomy it will be necessary to study the modifications of the uterine structure caused by pregnancy, labor, and the puerperal state. 3. There is nothing to be added to the symptomatology, except to note that inversions unaccompanied by hemorrhage may be explained by a hyperexcitability of the sympathetic system which distributes branches to the uterine vessels (vasoconstriction). 4. The partial or total uterine inertia that follows parturition must not be confounded with structural weakness of the uterus. 5. Inversion is due to two causes—the one predisposing, and the other determining. 6. The determining causes are so many that the mechanism of the production of inversion cannot be arbitrarily determined, but must vary in different cases.

Subcutaneous Emphysema during Labor.—Subcutaneous emphysema occurring during the second and third stages of labor and causing enormous distention of the face, neck, and thorax as far as the third rib, has been observed by G. L. Freeman,[7] and at a meeting of the Paris Obstetrical Society (Jan., 1896) Macé reported a case in which, about 2 hours before the child would have been expelled, the patient suddenly felt a pain in the left breast; then rapidly the neck and cheek became the seat of tumefaction to the extent of interfering with the movements of the eyelids. To prevent the aggravation of these symptoms by the efforts of the patient the labor was terminated by the application of the forceps. The emphysema

[7] Lancet, Mar. 14, 1896.

disappeared in about 2 weeks. Macé called attention to the rarity of this condition.

Sudden Maternal Death.—Postmortem Cesarean section with the extraction of a living child is reported by Hoffmann[1] and E. P. Davis.[2] Remy[3] advises in case of sudden death of a pregnant woman that an effort be made to save the life of the child. Three plans have been suggested: (1) to perform postmortem Cesarean section; (2) to do Cesarean section while the mother is yet alive; (3) to employ means to expedite labor and to extract the child by the natural passages as speedily as possible. Prunshuber's statistics show that when the mother is allowed to die before the child is extracted by abdominal section only about 5% of the children survive. Puech's statistics are somewhat more favorable; but there can be no doubt that the chance of obtaining a living child under these circumstances is very small. The performance of Cesarean section upon a dying woman who is unable to give her consent to the operation is undoubtedly open to sentimental objections. Gusserow and Manasse consider that the operation is justifiable under the following conditions: (1) when it is clearly proved that the mother is about to die, and (2) that the child is alive. Remy favors the plan of rapid dilatation of the cervical canal and extraction of the child per vaginam. Violent measures should be avoided, and the dilatation should be proceeded with as slowly as the condition of the mother will permit. The cervix may be dilated by means of Champetier de Ribes's bag or by the hand alone. If traction is made upon the bag, dilatation may be produced in less than half an hour.

FETAL DYSTOCIA.

Occipitoposterior Position.—When the head is above the brim, Currier[4] states that it is quite possible in some cases to rectify the position with the hand, the vectis, or the fillet—this, of course, in wide pelves; forceps may then be applied and the head extracted. If the head is in the pelvis, several methods are available—either traction with the forceps, perforation (if the child be dead or the head very large), or symphysiotomy. Warren[5] summarizes plans for the delivery of occipitoposterior positions as follows: In the first stage—1. As a prophylactic, the knee-chest posture; 2. with good flexion, temporizing; 3. manual version forward; 4. podalic version; 5. temporizing, and later low forceps; and 6. high forceps at the brim. In the second stage—1. Flexion with the finger and descent with the vectis or forceps; 2. rotation forward with the forceps; 3. reversed forceps; 4. forceps. Baldwin[6] urges manual interference in these cases, as suggested by Parry in 1873. He reports 8 successful cases and 1 partially so, and emphasizes the absolute necessity of complete chloroform narcosis before attempting to elevate the presenting part. Rosenberg[7] prefers to apply forceps, making the

first traction in a horizontal direction (with possibly a slight downward inclination), until the large fontanel can be felt under the pubic arch; the handles of the instrument are then gradually raised to deliver the occiput, and when this is accomplished the birth of the face follows easily upon a depression of the forceps into the first position. Zweifel[1] in impacted cases with fetal death recommends decapitation by Braun's blunt hook.

Multiple Pregnancy.—Interesting cases of twin pregnancy are recorded as follows: DeLee,[2] a case in which the sac of the first child contained a gallon of water, and the child presented by the face (L. M. A.); a living child was extracted by forceps. The second child presented transversely, and was delivered alive by version. There were two placentas adherent by a wall of decidua. The children were both males; Kahn,[3] a case of twin pregnancy with two placentas, that of the first child being prævia. The patient stepped out of bed on the 11th day, developed a heart-clot, and died on the following day; Heiman,[4] a case with maceration of 1 fetus, the other surviving; Ulecia,[5] a case of twin confinement with mummification of 1 fetus. The mother, a 23-year old multipara, developed purpuric spots at the fifth month of pregnancy. These disappeared under treatment with iron, but later signs of antepartum septicemia occurred. The fever continuing despite treatment, labor occurred prematurely. After the birth of a living fetus there was placental retention with syncope. The placenta was extracted manually, and with it came a mummified fetus of 6 months. The placenta was single and gave insertion to the two umbilical cords. An intrauterine antiseptic injection was given, but signs of postpartum septicemia appeared. These, however, were overcome and the patient recovered. The living fetus died from tetanus some hours after birth; Goullioud,[6] a case of double pregnancy in a double uterus, abortion occurring at the third month [cases of double uterus and double pregnancy are not common; Pozzi has collected 3 cases from literature]; and Moseley,[7] a case in which 1 fetus was intrauterine and the other tubal. (See *Extrauterine Gestation.*) Pujol[8] reports the case of a patient, aged 24 years, who was admitted to the hospital in the pregnant condition. On examination it was found that the membranes had ruptured, and that the patient was probably pregnant with a very large child or with twins. Dilatation of the cervix proceeded until it was possible for the attending physician to make a thorough examination, when the knees of a small child were found presenting, and the fetus was readily extracted. The second child had the usual presentation, and was born without special difficulty. It was found that one child had perished some time previously, and that its head had been greatly pressed upon by the second, larger, and living child. The second twin had survived the death of the other without especial injury. A. W.

White[1] of Trinidad reports an interesting case of *superfetation* as having occurred on May 9, 1895: A female fetus 6 inches long was first delivered; from its size and appearance it was supposed to be about 4 months old. It was dark-colored like its mother. Soon after the removal of the placenta a full-formed, full-term female infant, which had all the appearance of a "white man's child," was born.

The influence of inheritance on the tendency to have twins is illustrated by papers by Bremner,[2] Von Speyer,[3] Macphail,[4] Cory,[5] and Wakley, Jr.[6] Bremner gives the following family history, which is vouched for by more than one of the relatives. He attended the mother of the last pair of twins, herself one of twins. There is no history of twin births in any of the husbands' families, as far as could be discovered:

S. = son; D. = daughter.

Cory, in a study of 17 cases of twins, finds that there was a history of twins among ancestors in 76% of the cases. Von Speyer states that the rarer forms of multiple pregnancy are undoubtedly hereditary. Stoker[7] records a case of quintuplets, and Vassali[8] an undoubted case of sextuplets. Stoker's patient was a healthy woman, 35 years old, 5 feet 1 in. high, and of slight build, whom he delivered of 5 fetuses in the seventh month of pregnancy, none of the children surviving. The patient's mother had on two occasions given birth to twins. The woman herself had been married for 6 years and had borne 4 children at full term, having no difficulty in labor. When she came under observation she computed that she had been pregnant for 6 months, and had had her attention attracted to the unusually large size of her abdomen. She complained of fixed pain in the left side of the abdomen, on which side she thought she was larger. Pains set in with regularity and the labor lasted $8\frac{3}{4}$ hours. After the rupture of the membranes the first child presented by the shoulder.

Version was readily performed; the child was dead (recently). Examination after the birth of the first child disclosed the existence of more than one remaining fetus. The membranes protruded and became tense with each contraction. The presentation was a transverse one. In this case also there was little difficulty in effecting internal version. The child lived a couple of hours. The third fetus was also enclosed in a separate sac, which had to be ruptured. The child presented by the breech and was delivered naturally, and lived for an hour. In the fourth case, too, the membranes had to be ruptured, and alarming hemorrhage ensued. Version was at once practised, but the chin became locked with that of the remaining fetus. There was some difficulty and considerable delay in freeing the children, though the extent of the locking was not at any time formidable. The child was dead (recently). The fifth fetus presented by the head and was delivered naturally. It lived for half an hour. The placenta was delivered about 5 minutes after the birth of the last child, and consisted of two portions united by a narrow isthmus. One, the smaller, had two cords attached centrally and close together; the other, and larger, had two cords attached in a similar way and one where it was joined to the isthmus. The organ appeared to be perfectly healthy. The cord of the fourth child was so short that it had to be ligated in the vagina. The children were all females, and much about the same size, making a total weight of 8 lbs. The mother rallied quickly and made a good recovery. Vassali's patient, who was 36 years old, grew anemic and weak in the early months of her pregnancy, and complained of chilly feelings. She did not feel motion. In the fourth month the abdomen was as large as that of a normal pregnancy at term, and the woman daily expected confinement. On the one hundred and fifteenth day of gestation the membranes ruptured while straining at stool, and a foot prolapsed. Before this she had experienced no pain. A fetus was delivered. The next morning pains began, with chills, flowing, rise of temperature, and vomiting, and it was decided to terminate her pregnancy. The membranes were ruptured, a foot brought down, and a second fetus was delivered. A third bag of membranes presented, and a third fetus was delivered, and so on till the fifth. The process lasted 2 hours, when an endeavor was made to hasten what was thought to be the third stage of labor, but the attempt to remove the placenta revealed a sixth amniotic sac and fetus. All the fetuses were born alive and moved vigorously. The sexual organs were differentiated, 4 being males and 2 females. The large single placenta bearing the six amniotic sacs was unfortunately so lacerated that further investigation was useless. The specimen is preserved in the museum of the Obstetrical School at Milan.

Excessive Size of the Fetus.—Bennett[1] records a stillborn male fetus weighing 14 lb.; Woodward,[2] a living female fetus weighing 11 lb. 10 oz.; and Brothers,[3] a stillborn fetus weighing 14.3 lb., the mother also perishing 48 hours after labor. Goenner[4] has made an extensive series of observations upon the heads of children to determine the factors that produce the predom-

[1] Lancet, Jan. 11, 1896.

[4] Zeit. f. Geburtsh. u. Gynäk., Bd. 33, H. 1, 1895.

inant features in the child's cranium, and to ascertain methods by which the size of the cranium may be inferred before labor. He concludes that in the majority of cases the cranium of the child resembles that of the parents. This undergoes change during the process of birth, but the resemblance develops continuously when the child recovers from birth-pressure. The heads of newborn children are much narrower at birth than later. As regards the resemblance that the child's head bears to one or other parent, it is impossible to say that either parent determines the shape of the child's head. Hereditary peculiarities may be present, dating back to grandparents. At present we possess no accurate means of foretelling peculiarities in contour in the fetal head. Palpation and internal examination remain our only methods of obtaining knowledge. Phanomenoff[1] draws attention to the difficulty of delivering large children by reason of impaction of the shoulders. When he has failed to deliver by rotating the shoulders into an oblique diameter of the pelvis, he has had good success by performing double cleidotomy, cutting both clavicles with blunt-pointed scissors; the left hand is introduced as a guide, and each clavicle severed at its inner end. The scissors must be curved at an angle in order to accommodate themselves to the pelvic canal.

Shoulder-presentation.—Cases of spontaneous evolution during labor are recorded by Grasemann[2] in a slender primipara, the child having recently died, and being at term and of average length; and by Gomberg.[3] In neglected shoulder-presentations Kehrer[4] states that the *vis a tergo* acting upon the head and breech of the fetus produces a kyphoscoliosis; the thorax and abdomen form a cone, which, crowded through a dilated cervix uteri, is impacted in the true pelvis. The treatment, if the infant be alive, consists in forcing the flexed portion back toward the fundus uteri to straighten it, then to push it toward the side where the head lies, in order to perform podalic version; if the child be dead, embryotomy is necessary. [The danger of uterine rupture must be remembered in performing this maneuver.]

The Causation of Face-presentation.—In an exhaustive monograph Muggia[5] discusses the various alleged etiologic factors in face-cases, and gives in a tabular form the details of 41 such labors. The frequency with which these confinements occurred was once in 137 cases (41 in 5644 labors), and of the 41 instances met with, in 25 the chin of the child was to the back and right side, in 2 it was to the front and left, in 2 to the back and left, in 2 to the front and right, and in 5 it lay transversely and to the left. Among the fetal causes for the presentation found by Muggia were fetal struma, coiling of the cord round the neck, dolichocephaly, absence of the cranial vault, small size of the fetus, oblique position of the fetus, maceration, increase in the biparietal diameter, abnormal size of the head, abnormal shortness of the neck, and the female sex. The maternal causes included repeated pregnancy,

[5] Ann. di Ostet., Sept. and Oct., 1895.

hydramnios, uterine obliquity, uterine tumors, low implantation of the placenta, and pelvic contraction. It would seem that the fetal causes are the more important, and heredity may even come into play. A practical conclusion is that, if a face-case evidently represents the expression of given anatomic conditions, maternal and fetal, the intervention of the obstetrician is in the great majority of cases unnecessary. The genupectoral position of the patient in labor is advisable in order to aid the rotation of the chin. All external and internal manual interference should be undertaken only in definitely ascertained cases and under certain circumstances, for the fetus which presents by the face will often come safer thus into the world than if its presentation is modified. In only 1 of the author's cases was an asphyxiated infant not resuscitated. Of course it would be absurd to say that a face-case is more favorable than a vertex: at the same time, under the circumstances, presentation by the face may be a natural way of escape.

Retention of Urine in a Fetus.—Devé[1] states that he found nearly 7 pints of urine in the distended bladder of an 8 months' fetus; nearly 1 in. of the urethra was reduced to an impervious fibrous cord, and the rectum ended in the bladder. The urine contained only 0.024 milligrams of urea to the liter. Porak[2] relates the case of double hydronephrosis due to an incomplete valvular stricture of the membranous part of the urethra, and in a similar case to Devé's the urine was as deficient in urea. [This would seem to prove that the fetal kidneys probably eliminate nothing but water, with sodium chlorid in the proportion which that salt holds in the blood, and that the true renal functions in intrauterine life are discharged by the placenta.]

Funic Prolapse.—Brothers[3] has tested the Trendelenburg posture in the treatment of prolapse of the cord in 3 cases, and has succeeded in saving all the children. He claims that the cord can be replaced with much greater ease by this method than by placing the woman in the knee-chest posture.

Enormous Distention of the Fetal Abdomen.—Neumann[4] applied the forceps in a primipara on account of the arrest of the progress of labor. The birth of the head was easy, but the rest of the body did not follow, in spite of vigorous traction upon the head, which finally tore off. Neumann then passed his hand into the uterus and found the abdomen enormously distended with fluid, which made its entrance into the pelvis impossible. After its puncture the body was easily delivered. A postmortem examination showed a rudimentary formation of the external genitals and the absence of urethra and anus.

OBSTETRIC OPERATIONS.

Forceps.—Wahl[5] gives the statistics of forceps operations done in the Königl. Frauenklinic of Dresden during the 5 years from 1889 to 1894, as follows: The forceps were applied 232 times in 9061 deliveries, or in about

[1] Ann. de Gynéc. et d'Obst., June, 1895. [2] Jour. de Méd. de Paris, June 23, 1895.
[3] Am. Jour. Obstet., No. 6, 1895. [4] Monatsch. f. Geb. u. Gyn., Bd. iii. H. 3, 1896.
[5] Arch. f. Gyn., vol. 50. No. 2.

2.56% of the cases. In 29.3% of the cases the operation was done in the interest of the mother; in 65.9% in the interest of the child; and in 5.5% for both mother and child. 81% of the mothers were more or less injured by the operation, and 18.9% developed a high fever. The total mortality was 5.17% for the mothers and 21.2% for the children, but in no case was the death of the mother directly due to the operation, and only 5.6% of the children died from that cause. [These statistics do not differ essentially from those of other clinics]. Shick[1] gives the results of the use of forceps in 2920 labors. Birth was completed by forceps in 3.63% of cases, most of these being primiparæ. In 60% of the cases the mother was lacerated. The maternal mortality was 4.7%, while 11.32% of children perished. Of the mothers, 1.8% had septic infection. Shick concludes that the forceps is the bloodiest method of delivery, and that its mortality-rate renders it a serious procedure for mother and child. The advantages of Walcher's position in forceps operations and in all cases in which there are minor grades of pelvic contraction are emphasized by Fothergill,[2] Currier[3] and Johnston.[4] By its employment a spontaneous delivery may follow when otherwise forceps would be required. Fothergill states that by allowing the legs to hang the weight of the limbs will be transmitted to the innominate bones, causing a rotation of the pelvic girdle about an axis passing through the two sacroiliac joints, and when the symphysis moves downward in their rotation the conjugate is increased. The increase in the diagonal conjugate may reach 1.2 cm., the average increase being 0.93 cm. In other positions the chief power in forcing the symphysis down is the contraction of the uterine and abdominal muscles. Much of this force or energy is saved by the weight of the limbs, and the pressure of the head on the symphysis is avoided. When the legs are allowed to hang the perineum is not put on the stretch, and hence the danger of laceration is generally diminished. The position saves the perineum from undue pressure by forceps, especially when high forceps are used. Currier gives as indications for the use of Walcher's position: 1. Cases of protracted labor in which the dimensions of the pelvis are normal or the anteroposterior diameter is somewhat shortened, the head being above the brim; 2. Cases in which version, either cephalic or podalic, has been performed, or footling or breech cases. The flat pelvis, the generally contracted pelvis, transverse positions, and occipitoposterior positions are in this category; 3. Cases in which some form of operative procedure has already been adopted without success.

Symphysiotomy.—Cases are reported as follows: Dawbarn,[5] 1 fatal case, the patient dying of shock 7 hours after the operation; Cameron,[6] 1 successful case; Jewett,[7] 1 successful case; Treymann,[8] 3 successful cases;

Hirst,[1] 2 successful cases, 1 for concealed hydrocephalus, and the other for general pelvic contraction; T. E. Taylor,[2] 1 successful case in a woman whose 4 previous labors had been terminated by craniotomy; Ayers,[3] 4 successful cases, 1 being a twin birth, both fetuses surviving (the only twins delivered by symphysiotomy that have lived); Pomeroy,[4] 1 successful case; Auvard,[5] 3 successful cases; Abilio di Marcarenhas,[6] 1 successful case; Lowoff,[7] a fatal case in a tertipara aged 29 years, with a rachitic pelvis, the external conjugate being 16 cm. and the true conjugate $6\frac{1}{2}$ cm.; in her first pregnancy she had been delivered spontaneously of a dead child, and in the second pregnancy a living child was secured after a difficult labor; the patient died of dysenteria septica on the thirteenth day after operation; Walter,[8] a successful case in a secundipara aged 29 years, with a justominor pelvis, the true conjugate measuring 7 cm. Her first labor had resulted in a craniotomy; in the present labor the child lay transversely, one hand prolapsed, the cord pulsating; on account of the pelvic contraction it was impossible to introduce the hand into the uterus and perform a version; symphysiotomy was therefore decided upon, whereupon version became easy, but the after-coming head could only be extracted after prolonged manipulation, notwithstanding the fact that the fetus was premature (34th week); the child perished, but the patient recovered after 40 days, retaining, however, a vesicovaginal fistula which was subsequently closed; Lauw,[9] a successful case in a secundipara with a true conjugate of $8\frac{7}{10}$ cm.; the first labor had resulted in a craniotomy; in the present pregnancy the child lay transversely; a living child was extracted after symphysiotomy, and the mother made a good recovery; Gorochow and Chlebnikow,[10] a successful case in a quartipara aged 24 years, the diagonal conjugate measuring 8 cm.; in the first 2 confinements dead children were extracted after prolonged labors; the child in the third labor lay transversely; version was performed and the after-coming head perforated; in the present instance the head presented and the hand prolapsed; forceps were applied after symphysiotomy and a living child extracted; the mother made a good recovery; F. H. Sweeny,[11] 2 successful cases; A. B. Tucker,[12] 2 successful cases; and E. E. Ellis,[13] 1 successful case. Edgar[14] reports a bad result from the operation; the woman had become septic, and there had resulted necrosis of both surfaces of the horizontal rami of the pubes, the gap finally filling with fibrous tissue. Auvard's method of proceeding is different from that of other operators, in that he first applies forceps, and, failing to deliver, performs symphysiotomy without removing the forceps. [The advantage of this method is not evident.] Pinard[15] publishes some further records of high value on symphysiotomy.

In 4 years 69 cases of pelvic contraction have been treated by this method of temporary enlargement of the pelvic diameters at the Baudelocque Clinic; 62 mothers and 61 children were saved, 7 mothers and 8 children being lost. Geuer[1] records a case of symphysiotomy in a primigravida with failure of the bones to close. This was remedied by an osteoplastic operation after recovery from the labor. In order to keep the pubic bones in apposition after symphysiotomy Tarnier[2] uses a belt of India rubber covered with linen. The belt is placed under the loins of the patient, and is suspended by cords that cross above the bed and pass through pulleys attached to the frame of the bed. By attaching weights to the cords the pressure on the iliac bones may be increased or diminished at will. This apparatus permits the patient being moved about in the bed.

Queirel[3] of Marseilles has examined 200 women to determine the question as to whether the pubic joint is in the median line of the pelvis or whether it is often to one side. This investigation was undertaken because, in performing symphysiotomy, operators have failed to find the joint, and have in some instances cut through bony tissue, asserting that the joint was ossified. Of these 200 women, 135 had borne children, 65 had not. Their ages ranged from 20 to 89 years. He found between the ages of 31 and 40 in 39 women examined that the joint was 4 times upon the left of the median line and in 5 patients upon the right. In 50 women whose ages varied between 21 and 30, in 7 there was a deviation to the left, in 6 to the right. At other ages deviation was found in less frequency. In all, in the 200, in 20% the joint was not in the median line. An examination of the records of large numbers of symphysiotomies shows that the pubic joint is very rarely ossified.

Cesarean Section.—Cases are recorded as follows: Elder,[4] a Porro operation for labor complicated by uterine fibroids in a primipara of 35 years; the patient recovered; G. Haven,[5] 1 successful case; H. C. Coe,[6] 1 successful case; Abel,[7] a successful Porro operation after ventrofixation; Schwartz,[8] a successful Porro operation in a rachitic pelvis; Tschudy,[9] a Porro operation in a case of uterus didelphys in a primiparous woman of 30 years; the unimpregnated uterus was left in situ; Slocum,[10] a Sänger operation in a young colored girl of 16½ years with extreme pelvic contraction; Wysor,[11] 3 cases, 2 for pelvic contraction and 1 for uterine fibroids; 2 of the women died; Mayo,[12] a Porro operation for uterine fibroids, with recovery; Hunter,[13] a Porro operation for uterine fibroid; Wordin,[14] a Porro operation for uterine fibroid in a primipara of 39 years; Row,[15] a Sänger operation in a multipara whose entire genital tract was the seat of very deep and extensive tertiary syphilitic

ulcerations; the woman died of exhaustion 2 days later; Hirst,[1] a Porro operation in a primipara with contraction of the pelvis; Haskin,[2] a Porro operation in a woman upon whom, 2 years previous, a Sänger operation had been performed; both mother and child survived; Coakley,[3] 2 Sänger operations on the same woman 2 years apart for pelvic contraction; Ludwig,[4] a Cesarean section for labor in a kyphotic pelvis with an exostosis over the symphysis in a patient 28 years of age; Paton,[5] a fatal Sänger operation in a primipara with pelvic contraction; and Sänger,[6] a remarkable case of conception through an accessory ostium tubæ, with absolute obstruction to the delivery of the child by a former ectopic gestation filling the entire pelvic cavity, and necessitating a Cesarean section.

The technic of the improved Cesarean section as employed by Garrigues[7] is as follows: An incision is made in the median line half above and half below the umbilicus, as in other abdominal sections, just long enough to turn out the uterus, and, on account of the elasticity of the abdominal wall, that means that the opening is much smaller than the uterus, about 6 or 7 inches. The right hand is now introduced into the abdominal cavity and used to turn out the uterus, seizing it in the region of the left corner. Next the upper part of the incision is closed with 3 or 4 silk sutures, an inch apart and going through the entire wall; this keeps the intestines and omentum away from the field of operation. A rubber tube is laid loosely around the cervix and the broad ligaments outside of the appendages, and crossed, but not tied, so that the assistant in charge of this constrictor can easily tighten it or loosen it according to circumstances. The uterus is enveloped in a sterilized cloth wrung out of hot sterilized water, and a dry pad is placed in front of and behind it, to which it is well, if the waters are unbroken, to add a piece of gutta-percha tissue. Next, the elastic constrictor is tightened, and the operator incises the womb, the incision being made in the median line of the organ, clamping bleeding sinuses. The left index finger is introduced, and the incision extended on it with scissors or a probe-pointed bistoury up to the upper end of the cavity and far enough down to insert the hand and pull out the child, but *carefully avoiding the lower uterine segment*, where there are large veins and much less contraction than in the body of the organ. This incision is from $4\frac{1}{2}$ to $5\frac{1}{2}$ in. long. If the placenta is inserted on the anterior wall, the incision is carried through it. If the waters have not broken, the operator tears the ovum near the lower end of the incision, taking care that none of the fluid enters the peritoneal cavity, especially if it be decomposed or contain meconium. If the waters have drained off before the operation, the operator takes particular care not to wound the child in making his incision. When the ovum is ruptured the operator introduces his right hand and, if possible, delivers the head of the child first, whereby the danger of the uterus contracting in front of it is

avoided. If this is not easily done, he seizes an extremity or the body and extracts the child. The cord is tied immediately with a double ligature, and cut between the two ligatures, and the child is handed to a competent nurse or preferably a physician, who, if necessary, uses the usual means of reviving it. If the placenta is cast loose, the operator seizes it and peels off the membranes from the interior of the womb, so as to have all the after-birth in one piece. If, on the other hand, the placenta yet adheres to the wall, he leaves the after-birth alone and inserts the deep uterine sutures, by which time the placenta will probably have separated, but if it has not, he peels it off like the membranes, which always are adherent, before tightening the sutures. If the operation is performed before the cervix is dilated, this should be done manually, so as to ensure free drainage from the uterus to the vagina. For the sutures sterilized silk is the best material, a medium thick—No. 4 of the braided—for the deep, and a fine—braided No. 2—for the superficial. The deep are inserted $\frac{1}{2}$ in. from the edge through the peritoneal and muscular layer, but do not touch the endometrium. There should be one for each inch of the length of the incision. In tightening them the serous surfaces are merely brought together, and not drawn down between the edges, thus ensuring better coaptation of the muscular surfaces. When these deep sutures have been tied, superficial ones, only comprising the peritoneum, are inserted midway between two and two of the deep. They are likewise inserted $\frac{1}{2}$ in. from the edge, but are pushed out again $\frac{1}{4}$ in. from the latter, and inserted in a similar way on the opposite side, so as to apply broad surfaces against each other. After the removal of the after-birth the interior of the womb is simply wiped dry and clots are removed. No antiseptics are needed, nor should the uterus be curetted. All sutures being placed and tied, the elastic constrictor should be loosened very slowly, since a sudden rush of blood into the uterus is apt to cause hemorrhage. The uterus should not be replaced in the abdominal cavity before all bleeding has stopped. If there is any bleeding, it is checked by compression, or by pouring hot water over the outside of the uterus, or by adding supplementary sutures, or, if necessary, by administering an intrauterine injection of hot sterilized water. When all bleeding has ceased, the constrictor is entirely removed, the womb replaced, and the abdomen closed as after other abdominal sections.

PATHOLOGY OF THE PUERPERIUM.

Puerperal Sepsis.—[Apart from the serum-treatment of puerperal sepsis, intravenous injection of mercuric chlorid, and the advances that have been made in vaginal bacteriology, there is but little new in this department of obstetrics.] A new classification of puerperal sepsis, founded on a combined clinical and pathologic basis, and including not only the more familiar but the rarer forms as well, is offered by Dorland.[1] Clinically, heterogenetic puerperal sepsis is encountered in two main varieties—namely, that in which there has occurred a general systemic infection, and that in which the general

[1] Phila. Polyclinic, Apr. 11, 1896.

infection is subordinate to the local manifestations. Under these main divisions the various forms of sepsis are grouped according to their pathologic features:

A. Heterogenetic Puerperal Sepsis.

Class I. General Puerperal Sepsis.

1. Hemic or vascular infection.
   - (1) Puerperal septicemia. Synonyms: Sapremia (Duncan); resorptive fever; ptomainemia; ptomain-poisoning; ptomain-intoxication; septic intoxication; septic fever; putrid infection; putrid intoxication.
   - (2) Puerperal phlebitis (infectious phlebitis; septicæmia venosa) with thrombosis (thrombophlebitis) and embolism (puerperal embolism).
     - (*a*) Uterine and parauterine phlebitis (phlebitis uterina; puerperal metrophlebitis).
     - (*b*) Puerperal pyemia (septicopyemia; pyæmia metastatica; pyæmia multiplex).
     - (*c*) Puerperal (septic) pneumonia.
     - (*d*) Puerperal (septic) ulcerative endocarditis.
     - (*e*) Puerperal rheumatism.—Puerperal (septic) arthritis.
     - (*f*) Femoral (crural) phlebitis (phlegmasia alba dolens).
   - (3) Puerperal (infectious) erythema (scarlatiniform erythema).
   - (4) Puerperal (septic) infectious pemphigus.
   - (5) Puerperal tetanus (tetanus puerperarum).
   - (6) Puerperal neuritis.

Class II. Local Puerperal Sepsis.

1. Lymphatic infection (septicæmia lymphatica; puerperal lymphangitis).
   - (1) Puerperal metritis.
     - (*a*) Phlegmonous (metritis purulenta).
     - (*b*) Gangrenous (metritis gangrænosa).
   - (2) Puerperal pelvic cellulitis (puerperal parametritis, puerperal perimetritis, puerperal ovaritis).
   - (3) Puerperal peritonitis, pelvic or general (peritonitis puerperalis).
2. Involvement of the genital mucosæ.
   - (1) Vulvitis.
     - (*a*) Catarrhal or suppurative (vulvitis catarrhalis).
     - (*b*) Phlegmonous or ulcerative (vulvitis purulenta).
     - (*c*) Gangrenous (vulvitis gangrænosa).
     - (*d*) Diphtheric (vulvitis diphtheritica).
   - (2) Endokolpitis.
     - (*a*) Catarrhal or suppurative (endocolpitis catarrhalis).
     - (*b*) Phlegmonous or ulcerative (endocolpitis purulenta).
     - (*c*) Gangrenous (endocolpitis gangrænosa).
     - (*d*) Diphtheric (endocolpitis diphtheritica).
   - (3) Endometritis.
     - (*a*) Catarrhal or suppurative (endometritis catarrhalis).
     - (*b*) Phlegmonous or ulcerative (endometritis purulenta).
     - (*c*) Gangrenous (endometritis gangrænosa).
     - (*d*) Diphtheric (endometritis diphtheritica).
   - (4) Endosalpingitis.
     - (*a*) Phlegmonous or ulcerative (endosalpingitis purulenta; puerperal or septic pyosalpingitis).
3. Puerperal (septic) urethritis, cystitis, ureteritis, and pyelitis.
4. Puerperal (septic) proctitis.

B. Autogenetic Puerperal Sepsis (Autoinfection).

Döderlein[1] believes that the time has now come to abandon the old classification (catarrhal, purulent, diphtheric, and gangrenous), and to distinguish two forms of puerperal endometritis: Putrid endometritis, due to saprophytes, and septic endometritis, due to streptococci. Romme[2] states that the virulence of the vaginal streptococcus in a healthy pregnant subject not officiously treated by the obstetrician and midwife is equal to that of the streptococcus of other mucosæ; in other words, it is not virulent at all, and acts as a saprophyte on healthy tissues. But when the resistance of the tissues is diminished in the vagina, as in the intestine, the streptococcus can act as a parasite, and be as virulent as the special germ of the same genus that causes puerperal sepsis. Hence routine injections are deleterious in normal labor in which delivery has not involved true traumatism of the tissues, and digital exploration is to be avoided as far as possible, as vaginal streptococci might be introduced into the previously aseptic but naturally lacerated tissues of the uterus. On the contrary, vigorous disinfection of the vagina is indicated whenever exploration or operative intervention has to be carried above the level of the os externum and in all abnormal labors; it is also needed when the patient has an affection that diminishes the resistance of the tissues, as nephritis, cardiac disease without compensatory hypertrophy, syphilis, diabetes, intercurrent infectious maladies, and anemia. Fehling[3] states that absorption fever is not rare in patients suffering from gonorrhea during pregnancy, and pustubes are often noted. Bumm[4] has demonstrated that the fibrinous membrane forming upon the mucous surface of the genital tract during the so-called diphtheric cases of puerperal sepsis does not always contain the diphtheria bacilli, but streptococci in abundance. He reports a case, however, in which the diphtheria bacilli were present and the streptococci absent, probably due to the action of antitoxin which had been given in three injections. Solowieff[5] concludes that though intermittent fever is relatively rare during pregnancy and the puerpery, it may be the cause of abortion, premature delivery, or in some cases of the death of the fetus, and may be mistaken for puerperal sepsis. In all such cases treatment with quinin, opium, and arsenic is effective. Pearson[6] records a case of puerperal hyperpyrexia, the temperature on the evening of the fifth day reaching 107.4° F. after a sharp rigor; on the evening of the seventh day it was 106°. Acetanilid in full doses reduced the fever and the patient recovered. Bar[7] describes a rare case of gonorrheal rheumatism in the puerperal state, the patient ultimately making a good recovery. Balls Headley[8] records a case of puerperal pelvic cellulitis from phlebitis, followed by complete recovery without operation.

Delayed Puerperal Infection.—Doléris[9] points to the established fact that the bacilli of infection may be temporarily innocuous until some incident

again arouses their former virulence; thus it comes that an infection that has been latent for weeks or months suddenly flares up with surprising intensity. He refers to cases of mild puerperal infection that during the puerperium gave either very slight or no symptoms at all. Weeks later, owing to some influence unknown, the latent bacteria are again aroused to activity and produce serious symptoms of puerperal infection. Infection may also occur some time after labor or the puerperium, which may still have a puerperal character, because the sexual organs have not regained their former conditions, and still possess a special morbid receptivity. The treatment of delayed puerperal infection is in accord with antiseptic principles.

A rare form of puerperal sepsis (*endometritis diphtheritica dermatomyositis*) is recorded by Heinricius.[1] A pluripara was seized 3 days after a normal confinement with chills and high fever; during the next few days there was a stinking lochial discharge, but no symptoms of peritonitis; on both legs and forearms painful swellings occurred, the overlying skin being spotted and very sensitive. On the forearms were larger and smaller blebs containing clear serum. The patient presented the picture of marked sepsis, and succumbed on the tenth day. An incomplete postmortem examination showed the absence of peritonitis or parametritis. The endometrium was covered by greenish-yellow shreds. The corium, intramuscular connective tissue, and the muscles underlying the swellings of the extremities were soft and edematous, but pus was absent. Out of these tissues and the endometrium pure cultures of streptococci were obtained.

Puerperal Tetanus.—Cases of puerperal tetanus are reported by King,[2] Thomas,[3] Withington,[4] Walko,[5] and Rubeska.[6] Withington's case developed after an abortion, the patient suffering from repeated attacks of spasm, with opisthotonos; gradual improvement followed 3 injections of tetanus-antitoxin (22 ccm. each), in all 68 ccm. In Walko's case the antitoxin treatment was unsuccessful, the patient receiving in all 18 injections, comprising $3\frac{6}{10}$ grams. Well-marked leukocytosis developed after the second injection. Bacteriologic examination was negative. Extirpation of the uterus was practised in Rubeska's case without success, the patient dying on the fifth day. A fatal case of tetanus following delivery, which was accompanied by a slight laceration of the perineum, is reported by W. F. Sawhill,[7] and Drappier[8] records a fatal case in a secundipara due to the use of an intrauterine douche.

Phlegmasia Alba Dolens.—Mowat[9] records a case of phlegmasia alba dolens in a virgin of 18 years, while Herman[10] records a similar case, in which, however, both legs were involved consecutively. Roberts[11] read a paper before the Obstetrical Society of London in which he gave details of 16 cases of

so-called "white leg." He proposes the following classification: 1. Cases due to pressure; 2. Cases associated with general disease; 3. Cases of a true septic nature; 4. Cases of thrombosis apart from sepsis; 5. Cases of thrombosis and sepsis combined. He concludes that the common variety after delivery is the thrombotic, the thrombosis in most cases starting primarily in the uterine and pelvic veins; the brawny white leg is rare. The onset of the disease is about the tenth or twentieth day, and the cases run a definite course of about 6 or 8 weeks. The prognosis to life is good, but the prognosis to the leg itself is not good. Raymond[1] records a case developing on the ninth day and lasting for over 4 months.

Treatment of Puerperal Sepsis.—[The serum-treatment of puerperal sepsis has attracted considerable attention during the year, but sufficient statistics have not accumulated as yet to warrant the assumption of positive conclusions.] According to Imlach,[2] the researches of Bokenham in the experimental laboratory of the College of Physicians have apparently resulted in the discovery of a microbicidal serum that may be safely employed in early cases of septicemia with a reasonable hope of success. It is only at the very inception of septic fever, however, that we are to depend upon the action of the antistreptococcic serum. Gaulard[3] describes 2 cases of puerperal sepsis which he treated by injections of Marmorek's antistreptococcic serum—that obtained from animals immunized by injections of increasingly virulent *complete* cultures—with good results in 1, but death in the second case. The serum does not do away with the necessity of using the curet, but if the germs have already entered the blood, it may be employed against them and their toxins. Jacquot,[4] Vinay,[5] Macfarlane,[6] and Kennedy[7] report cases successfully treated by the serum. Vinay states that while the serum may be all-powerful against recent infection of the blood, it is inefficacious against once-established organic lesions. It is in instances of the former that the serum is indicated, and it should be administered at the time when the blood is invaded by the toxins of the streptococci and by the streptococci themselves. This treatment must not be employed alone, especially at the beginning, and should not exclude local treatment of the infected mucosæ. Furthermore, antistreptococcic serum is not efficacious in those forms of puerperal septicemia due to other bacteria than the streptococcus. The ideal method of studying these cases would be to make cultures from the cervix in each case, using the serum only in such cases as are thus shown to depend upon the streptococcus. In general, the most serious infections are due to the streptococcus, and if we have chills and a rise of temperature to 40° C., we may assume, almost with certainty, the presence of the streptococcus. It seems best to use the injections in the evening, when their effect will increase the spontaneous fall of temperature.

De Kesmarky[8] used intravenous injections of mercuric chlorid, $\frac{1}{6}$ gr. a

day for 20 days, in the treatment of puerperal infection. The patient died in 45 days from gangrenous metastatic abscess of the lung. In 2 other cases of puerperal infection he began with intravenous injections of $\frac{1}{65}$ gr., pushing it to $\frac{1}{12}$ gr. daily. The first patient received altogether a little over $\frac{1}{2}$ gr. in 10 injections; the second a little less than $\frac{1}{2}$ gr. in 8 injections. The temperature fell progressively from the beginning of the treatment. Both patients recovered. De Kesmarky states that this treatment is without danger and promises well.

The most modern treatment of general septicemia is that of hypodermic injections of creasote, recommended by Frank[1] of Cologne, Germany. This method has been employed by Mehrtens of Düsseldorf in a case of puerperal sepsis with remarkable results, the temperature falling from 104° F. to normal after the injection of creasote. A rise on the next day to 104° was again brought down by the injection, and subsequent injections, 3 times a day, prevented its recurrence. Mehrtens used a solution of equal parts of creasote and camphorated oil, of which he injected 20 minims thrice daily. None but good effects were observed.

The local treatment of puerperal sepsis, according to Pinard,[2] comprises intrauterine intermittent irrigation, continued irrigation, and curettage. Intermittent irrigation, first employed by Recolin and Levret, and recommended by Gensoul, Roche, and Lemuel Weiss in 1858, has become current treatment, especially since Pasteur revealed the true nature of infection. For this purpose Pinard uses the glass sound of Fariner, which is very easy to introduce, and, when ordinary precautions are taken, cannot break. The antiseptic liquid he employs is a solution of mercuric biniodid (1:4000) at 103° F. Being a partisan of low pressure, he places the reservoir containing the liquid for injection only 10 in. above the level of the patient, as in this manner the liquid cannot penetrate into the veins or the uterine sinuses. The amount injected generally exceeded 3 quarts, or until the liquid returned was quite clear. Continued intrauterine injection is entirely of French origin, but to a German, Shücking of Halle, is due the honor of being the first to apply it to obstetrics. Since 1885, Pinard has employed it frequently in his service. The method of operating is about the same as in the first case, but the sound is made of metal, as the glass might break. The antiseptic liquids are: a solution of mercuric biniodid (1:4000); a solution of phenol (1:100); a saturated solution of boric acid: 15 quarts of the first solution are injected, and followed by the second, and as soon as the temperature of the patient has come down to the normal it is replaced in its turn by the third. Objections have been made against this method, not only as regards the difficulty of adopting it in private practice, but also as regards the fact of leaving a sound *à demeure* for days and nights, which might produce an accident by the movements of the patient. Pinard considers that such a danger could only be feared where the instrument was not properly fixed to the patient. At any rate he never witnessed the slightest accident in all the cases in which he had tried it. The operation of

[1] Physician and Surgeon, Mar., 1896.

[2] Med. Rec., Nov. 23, 1895.

curettage followed by Pinard differs but slightly from that usually practised, with the exception of the absence of anesthetics and the nonemployment of the speculum. [For the surgical treatment of puerperal sepsis the reader is referred to the section on Gynecology.]

Puerperal Bradycardia.—Neumann [1] publishes his observations of the pulses of 500 women during the puerperium. According to Blot and other observers, bradycardia in the normal puerperium is due to an increased arterial tension and blood-pressure, owing to the sudden diminution of the uterine circulation. Olshausen believed it due to the absorption of fat from the degenerate uterus. Löhlein referred it to a disturbed innervation from an altered constitution of the blood. Swiecicki traces the alleged disturbance to chemical irritation of the uterine nerves as a part of the process of involution, which irritation in turn influences the vagus. Fritsch attributes the bradycardia to the mental and physical rest involved in normal labor. Schröder argues that after the suppression of fetal circulation the maternal heart, having less to do, contracts more slowly. Vejas considers the phenomenon in question due to an increased vital capacity of the lungs. Neumann concludes that puerperal bradycardia depends on stimulation of the cardiac inhibitory fibers, and arises through irritation of the vagus center during labor.

Postpartum Hemorrhage.—E. P. Davis [2] records a fatal case of postpartum hemorrhage due to an altered condition of the blood, general lack of muscular tonicity, and an inherited tendency to bleed. Leahy [3] records 10 cases of hemorrhage due to tonic spasm of the body of the uterus, an exceedingly rare cause of this accident. According to Mayne,[4] postpartum hemorrhage has been treated successfully a number of times by saturating a piece of lint in turpentine and introducing it by the hand into the uterus. No injurious results follow the use of this remedy.

Hematoma of the Vulva.—Cases of this rare condition are recorded by Goldberg [5] and Klautsch.[6] Cases of pelvic hematocele after labor are noted by Bliss [7] and Stadfeld,[8] the latter being a case of suprafascial pelvic hematoma, which, according to the writer, occurs almost without exception in primiparæ. It is due most frequently to the bursting of a blood-vessel in the connective tissue surrounding the vagina, with which it may communicate secondarily through rupture of the vaginal wall.

Superinvolution of the Uterus.—A case is recorded by Tingley.[9]

Puerperal Osteomalacia.—Neumann [10] has written a paper of high scientific value upon the excretion of magnesium, calcium, phosphoric acid, and nitrogen in puerperal osteomalacia, and the changes that are produced by castration and other therapeutic measures. He calculated in 3 cases of osteomalacia the amount of CaO, MgO, P_2O_5, and N in food taken by the patients,

and the amount present in the feces and urine. These investigations are divided into different groups—namely, before and after the establishment of therapeutic measures, and before and after castration or the removal *in toto* of the pregnant uterus. As a result of these investigations the following conclusions may be mentioned: 1. The excretion of calcium in the urine is greatest in the beginning of the disease, when the bones are yet rich in calcium salts; as the disease progresses the excretion diminishes. 2. The calcium excretion differs in the various stages and with the severity of the disease. 3. After the removal of the ovaries or of the uterus, the CaO, MgO, and P_2O_5 excretion becomes again normal in mild cases, while in severe cases neither operation exerts any influence upon the further progress of the disease. 4. The osteomalacia is not simply a bone-disease, but the disease-process extends upon and involves all tissue-changes. 5. The removal of the ovaries or of the uterus is only of benefit in mild cases and in the beginning of the disease. This operation should, therefore, be performed early, as soon as other therapeutics have shown their uselessness.

Puerperal Polyneuritis.—Vinay[1] states that polyneuritis occurs in the course of the puerperal state at two distinct periods—during pregnancy and after delivery. The latter form is the more frequent, and has become classic since the work of Möbius was published in 1887. Möbius believed that the neuritis after delivery was characterized by its localization in the ulnar and the median nerves, but observations do not lack showing that motor and sensory disturbances may affect all four extremities. The sole characteristic of these postpartum neurites is their identical pathology, all being the consequence of puerperal septicemia. Polyneuritis in pregnant women is much rarer. In the author's book on the treatment of the diseases of pregnancy (Paris, 1894) he has been able to cite but 3 well-authenticated cases of this affection. The case published by the author in the present paper was that of a woman 38 years old, who had given birth to 6 children and who had 2 miscarriages. During the first 3 or 4 months of her last pregnancy she had frequent hemorrhages. During the last 2 months she vomited a number of times and felt pains in the calves of the legs and formication in the hands and feet. The delivery was normal. On the fourth day after delivery the patient got up, but could not stand; she fell to the floor. At the same time she discovered marked weakness of the arms. She experienced paresthesia and considerable wasting in the extremities. The patellar reflexes were abolished. After $3\frac{1}{2}$ months' treatment, consisting of subcutaneous injections of ergotin and of electric baths, the improvement was sufficient to allow the patient to resume her customary occupations.

Pathology of the Breasts.—Toulouse,[2] in a contribution on puerperal psychoses, treats of those that are associated with sucking (*psychoses of lactation*). In rare cases these follow quickly on labor, but then they are hard to distinguish from simple puerperal psychoses. The majority occur after several months of suckling in poor and weakly women. A third form follows wean-

[1] Nouv. Arch. d'Obstét. et de Gynécol., No. 12, 1895. [2] Brit. Med. Jour., Feb., 1894.

ing. Slight mental disturbance may accompany abscess of the breast, but it is then due most probably to sepsis. Mental disturbance during lactation may begin in the form of slight delirium following mental shock or simply change of diet. As a rule, however, physical symptoms appear first. The patient becomes thin and pale, and palpitations, indigestion, and insomnia set in. In 25 cases noted by Macé there was melancholia in 11, mania in 11, and partial delirium in 3. The prognosis is favorable, 20 recoveries and only 2 deaths having been noted by the above-named writer. As in puerperal mania, auto-infection probably accounts for the phenomena of mental disturbance during lactation.

Van Tussenbroek [1] describes an unusually bad case of galactorrhea following an abortion at the fifth month in a primipara. Emaciation set in, and, as no therapeutic measures were of any avail, the mammæ were amputated. Microscopic examination did not explain more than might be expected, the glandular tissue being in a very active condition. Goldberger [2] records a patient who had 2 supernumerary mammary glands, 1 in the right axilla and the other beneath the left axilla; both glands were ductless, but aspiration by a Pravaz syringe showed that they both contained milk. Hirst [3] reports a case with an unprecedented number of breasts and nipples; the woman—a negress—had 9 mammæ, all told, and as many nipples; there were 5 on the left and 4 on the right side. [There is a total of 262 cases of accessory mammary glands described in literature, but none in which the number of glands was as great as in this instance.] Anthony [4] reports a case of diffuse hypertrophy of the breasts; and Norris [5] a case of submammary abscess. Gaudier [6] found in the milk of a patient who had nodules in the breast the *staphylococcus albus* in a pure culture. He injected this culture into the breast of a nursing bitch, and 2 days later single nodules were distinguished in the glandular structure of its breasts, which gradually developed into cystic cavities; he concludes, therefore, that these cysts form the final stage of the nodules.

PHYSIOLOGY AND PATHOLOGY OF THE NEW-BORN.

The Signs of Maturity at Birth.—Frank [7] concludes that there is no one sign or set of signs which by themselves are sufficient to establish maturity. He thinks the classical reliance upon the length of the finger-nails, the presence or absence of lanugo, and the size of the epiphyses is unsafe. A subnormal temperature in a nonasphyxiated child is in his opinion indicative of prematurity. To the attainment of average length and weight he attaches much importance. Finally, he believes that the proportion between the girth about the shoulders and the circumference of the head is of considerable value. When the shoulder girth is greater that that of the head, the child is usually mature. If the circumference of the head is not at least 32 cm. the child is

[1] Rép. univ. d' Obstét. et de Gynéc., Feb. 25, 1895. [2] Arch. f. Gynäk., No. 2, 1895.

[7] Arch. f. Gynäk., 1894, Bd. 48, H. 1.

almost certainly premature. [He concludes wisely that it is often not possible to decide positively whether a child is or is not at full term.]

Respiration in the New-born.—Dohrn,[1] from a series of examinations made upon new-born children to determine the extent to which respiration is carried, has found that on the average, during the first 10 days of life, a child respires 50 times to the minute. There seems to be no difference between prematurely born children and those at term, or between boys and girls, in the frequency of breathing. During crying an infant inspires less frequently than during regular breathing. Inspiration and expiration during crying vary from 47 to 62 to the minute. The average movement in expiratory respiration during the first 10 days of life is 45 ccm. The amount of air changed in respiration is the same in children of both sexes, but is less in prematurely born children. The depth of respiratory movements increases from the first to the tenth day of life, so that the expiratory movements during the last few days of the 10 are increased 12 ccm. The reason for this increase is found in the enlarged play of the ribs, the dilatation of the bronchial tubes, and the increased respiratory necessity of the child. The depth of respiratory movements is less in the new-born than one would expect. It is evident that the first respiratory movements do not unfold the lungs, but that this process is a very gradual one.

Asphyxia Neonatorum.—The successful employment of Laborde's method of rhythmic traction of the tongue in asphyxiated children is recorded by Erskine,[2] Russel,[3] and Cameron.[4] The treatment of asphyxia by inversion, a method first advanced by Nélaton, is urged at length by Bissell.[5] The effect of inversion effectually aids, by the action of gravity, the emptying of the contents of the liver into the heart, nourishing in turn that organ, and by the continued action of the same law the flow from the heart to the medulla is also materially assisted. Consequently, a greater quantity of oxygen is supplied to the nerve-center in a given length of time than would be if the body were kept in any other position.

Inanition Fever in the Newly Born.—Holt[6] reports a case of this nature, and remarks that the possibility of an infant which is being put regularly to the breast dying of starvation during the first few days of life is not one of those ideas which usually presents itself to the mind of the physician. The mother's breasts in the reported case yielded very little milk. Under a wet-nurse and the free administration of a prepared food the child rapidly improved. Observations have been made on the subject at the Sloane Maternity and the Nursery and Child's Hospitals, which have established the fact that it is not uncommon for the temperature to rise in the newly born during the first few days to 102° to 104° F., unaccompanied by any evidence of local disease, and that it falls again when the secretion of milk on the part of the

[1] Zeit. f. Geburtsh. u. Gynäk., Bd. 32, H. 1, 1895.
[2] Med. and Surg Rep., 1895, lxxii. 525.
[3] Therap. Gaz., Aug. 15, 1895.
[4] Montreal Med. Jour., 1895, vol. xxiii. No. 12.
[5] Med. Rec., Nov. 30, 1895.
[6] Am. Gynæc. and Obst. Jour., Oct., 1895.

mother is freely established. It is also arrested by proper artificial feeding. A rapid fall of temperature takes place, often to normal, in a few hours. At the Nursery and Child's Hospital, 20 of 200 infants, taken successively, had the fever during the first 5 days, and at the Sloane Maternity 135 out of 500 successive children born in the institution. The fever usually reached its highest point from the third to the fourth day. The average loss of weight amongst the healthy children was 10 oz.; this loss was exceeded in those children who had the fever by several ounces. The maximum loss was 28 oz. As a rule, when the temperature fell to normal the children began to put on weight. The symptoms are a hot, dry skin, marked restlessness, dry mouth, and a disposition to suck anything within reach vigorously, everything indicating extreme thirst—high temperature, considerable prostration, and weakened pulse. In the milder cases there is only unusual restlessness and crying. The symptoms disappeared with great rapidity when the children were nursed or fed. The main treatment, in addition to proper feeding, is to give water up to an ounce every 2 hours if required by the thirst of the child. This should be done in every case in which the temperature reaches 101° F. In case the temperature does not at once begin to fall, the infant should be put upon another breast or artificial feeding begun.

Scorbutus from Sterilized Milk.—Starck[1] points out the danger of scorbutus following a prolonged use of highly sterile milk. He calls attention to the fact that the presence of certain kinds of bacteria in the milk is not harmful, as even breast milk is not always free from bacteria. He would limit the use of sterilized milk to seasons of very hot weather and to the dwellings of the poor.

Nephritis in the Newly Born.—Jacobi[2] describes cases of this disorder in infants, and summarizes his observations as follows: Nephritis is not rare in the newly born. The use of the centrifuge enables us to recognize cases of nephritis in infants which were formerly considered simple or transient albuminuria. The fragility of the blood-vessels, the small size of the renal capillaries, the inability of the infant's intestine to expel toxic contents, and the large size of the lymphatics and blood-vessels of the intestine all favor the absorption of toxins, resulting in nephritis. The principal forms of this condition in infants are the congestive, resulting from feeble heart, asphyxia, and exposure; the obstructive, from rapid decomposition of the blood, with the formation of retrograde products; and the irritative, caused by infarctions of uric acid or hematoidin, by purpura or intestinal hemorrhage, or the microbes and toxins of enteritis and of infectious maladies.

Tetanus Neonatorum.—Dorland[3] reports a case of tetanus of the newborn child, the infant being of colored parents; the disease developed on the fifth day, and terminated fatally on the morning of the seventh day.

Vaginal Secretion of New-born Infants.—Vahle[4] gives the results

[1] Münch. med. Woch., No. 42, 1895.
[2] N. Y. Med. Jour., No. 3, 1896.
[3] Phila. Polyclinic, Aug. 24, 1895.
[4] Zeit. f. Geburtsh. u. Gynäk., 1895, Bd. 22, H. 3.

of his examination of the vaginal secretion of new-born infants to determine the presence or absence of bacteria. He finds that for 2 hours after birth the vulva and vagina are sterile. From this time until the third day germs are occasionally found, and after the third day they are present in most cases. In 4% of cases staphylococci were discovered, while in 14.6% streptococci were isolated.

Icterus Neonatorum.—Schreiber[1] writes on Quincke's theory of the origin of icterus neonatorum. Quincke has declared for the old explanation of Peter Frank's, that the icterus of the new-born arises from absorption of bile from the contents of the large intestine, and he has supported it on new grounds. The chief point is the patency of the ductus venosus Arantii, through which the absorbed bile-pigment reaches the body without having to pass through the liver. To this is added "the increased secretion of bile-pigment owing to the destruction of numerous blood-cells, the irregular relations of urinary secretion in the new-born, the richness of the meconium in bile-pigments, and the absence of reduction of bilirubin to urobilin, owing to the want of intestinal decomposition." Schreiber holds Quincke's theory as a very happy explanation, and supports it against the attacks of Kehrer and Stadelmann.

Ophthalmia Neonatorum.—Budin[2] again recommends the prophylactic treatment of ophthalmia neonatorum by silver-nitrate solution of 1 : 150 strength; in his hands it has given most satisfactory results. Of 2004 children treated with this solution, there were only 2 cases of purulent ophthalmia and 7 of secondary conjunctivitis. These results may be explained in part by the precautions taken. These include a bath and vaginal injection of mercuric chlorid 1 : 4000 before confinement if this be not too far advanced; drying the infant's eyes and introducing several drops of the 1 : 150 silver-nitrate solution just after birth; and immediate isolation of the mother and child if the slightest complication occur in either.

Skin-diseases in the New-born.—Schmidt[3] reports 3 cases of the rare fetal malady, sclerema neonatorum. In the blood of all these children bacteria were isolated. The capillary vessels were crowded with round bacteria, which were also found free in the connective tissue. These germs were also present in the parenchyma of the lungs and in the subcutaneous fibrous tissues. [It is probable that this disease may properly be considered an infection, but further bacteriologic researches are desirable.] Cabot[4] reports the case of an infant, 14 months old, suffering from congenital ichthyosis. This case was of unusual interest from the length of time which the child survived its birth. Born at the seventh month, it did not die until the fifteenth month of its life. H. M. Morton[5] records a case of dermatitis exfoliativa neonatorum (Ritter's disease), in which the epidermis exfoliated at 3 different times, the infant eventually recovering completely.

GYNECOLOGY.

By J. MONTGOMERY BALDY, M. D., and W. A. NEWMAN DORLAND, M. D.,

of Philadelphia.

Principal Features of the Year's Work.—It is doubtful whether in any other department of medicine more important advances have been made or more vital questions discussed during the past year than in abdominal and pelvic surgery. Aside from the pressing points of dispute in the major operative procedures which have distracted the gynecologists during the past two or three years, and which are as yet unsettled in all their details, other subjects of no less interest, although not involving the use of the knife, have claimed more than the ordinary amount of interest and attention. Bacteriology has made a great advance in gynecologic work, and the microscope is now to be recognized as an important aid in the forming of gynecologic diagnoses. Not only has it been of service in the recognition of early stages of the various forms of malignant uterine diseases, but by its use the rarer and semimalignant—as they may properly be called—forms of ovarian cystomata, the ovarian papillomata, may be recognized, and the presence of tubercles in the uterus, tubes, and ovaries demonstrated. Stroganoff and others have employed it in the study of the uterine and cervical secretions; Döderlein in his investigations upon the normal and pathologic secretions of the vagina, both of nonpregnant and pregnant women; and others as a means of diagnosis and guide to treatment in their study of the contents of tubal retention-cysts and ovarian abscesses. The changes in the uterine mucosa subsequent to the operation of castration have also been studied under the eye of the microscope, and valuable contributions to our knowledge made. The importance of urinary analysis as an aid in diagnosis and a guide to the institution of proper methods of treatment has been enlarged upon. By proper attention to this exceedingly valuable means of diagnosis the most appropriate time for operation may be selected, and in nonoperable cases the most suitable dietary selected and many of the distressing clinical manifestations corrected. Cystoscopic examination of the bladder and catheterism of the ureters and kidneys are fully established as more delicate means of differentiating between the obscurer pathologic conditions of the urinary tract in women; and this hitherto but little explored region of the organism is steadily yielding up its mysteries to the indefatigable workers in this line of pelvic surgery. The

methods of cystoscopy and ureteroscopy have been much perfected and facilitated during the twelve months just elapsed. Bicycling for women, after passing through a storm of active opposition on the part of the nonprogressive and ultraconservative obstetricians and gynecologists, is now recognized as one of the most valuable and tangible methods of securing the necessary amount of out-of-door exercise. Like all other agents for good, it is as potent for evil if abused or used in excess, and the teaching of the day is to encourage the proper posture to be employed and the most suitable saddle and instrument to adopt. The literature of the subject is as yet very scanty, but that which is accessible is of the highest order of merit, and shows that the new variety of physical culture is getting a hold upon the minds of the most competent observers in gynecologic and obstetric work. Finally, as may be expected, the recently agitated subject of vaginal major surgery has been prominently before the mind of the gynecologist. Hysterectomy by the vagina for pyosalpinx and other morbid conditions of the adnexa; the operation of anterior kolpotomy for the relief of uterine displacements and ovarian and tubal disease, including extrauterine gestation; and the operation of vaginal celiotomy—all have offered themselves as substitutes for the time-honored abdominal section. While they have won for themselves appreciable numbers of enthusiastic followers, abdominal section still continues as the sheet-anchor of pelvic surgery, and doubtless will so continue as long as the knife of the surgeon is in demand for the relief of the peculiar woes to which womankind is subject.

PRELIMINARY AND GENERAL CONSIDERATIONS.

Neurasthenia in Women.—Probably the most distressing condition into which a woman can fall is that described under the various captions of neurasthenia, nerve-exhaustion, or the invalid habit, although A. J. C. Skene[1] regards the latter condition as quite distinct from hysteria, neurasthenia, and fancied ailments such as occur among those given to introspection. He states that disappointed maids and "spoiled" wives form the largest number of those afflicted with this complaint. They complain of strange nerve-symptoms, general weakness, and obscure pelvic pains that incapacitate them for any kind of mental or physical work. As a rule, they have suffered from some real affection which they cling to long after recovery. The only derangement usually found is the lax, soft tissues that come from disuse. He regards the direct causes as twofold—either over-treatment of slight affections of the pelvic organs or unsuitable treatment of trivial affections of the nutritive and nervous systems. He believes that the rest-cure, with forced feeding, so often employed in cases that do not require it, is responsible for many examples of the invalid habit. On the contrary, this condition should be treated with the occupation-and-exercise cure, and with well-regulated gymnastic and mental exercises. Skene believes that dancing, carriage-riding on moderately rough roads, and horseback riding are better borne and

[1] Brooklyn Med. Jour., Sept., 1895.

more suitable than the less active exercises. He would prefer dancing to walking, and horseback riding to bicycling.

Neurasthenia proper, according to Frederick,[1] is an exhaustion of the nervous system—especially the sympathetic nervous system—due to malnutrition, systemic poisoning from pus, the nerve-depressing influence of constant pain, or the continuous drain of blood or mucopurulent discharges. These are the cases most suitable for the Weir Mitchell rest-treatment carried out quite rigidly. Lithemia, also, as indicated by Mann,[2] may be responsible for this condition, and an examination of the urine in these obscure cases may reveal the true condition when other diagnostic measures have failed. Some of these women suffer from severe neuralgic attacks, and Cumston[3] states the following types of neuralgia as those most frequently met with in association with uterine lesions: 1. Facial; 2. Intercostal; 3. Sciatica; 4. Abdominolumbar. [The neurasthenic is one of the most distressing patients with whom the gynecologist is called upon to deal, and any investigations that will throw light upon the proper management, hygienic and therapeutic, of this disease, if such it may be called, will be more than welcome. Unfortunately these patients are generally undesirable, and wander from doctor to doctor with but little resultant improvement in their condition.]

Functional heart-disorders are occasionally noted, John D. Williams[4] having found 25 cases in a little over 300 women whose hearts and pelvic organs he has examined during the last 6 years. Of these 25 cases, the uterus was affected in 11 instances, in 8 it being displaced in various directions. The other 3 women were suffering from uterine fibroids. Two of the 25 cases were instances of cervical stenosis, and in 6 cases the lesion was ovarian; 1 suffered with vaginismus, 2 from anal fissure, and of the remaining 3, 1 had tachycardia following an attack of influenza and pelvic peritonitis; the second had coccygodynia; and the third a floating kidney. In all of these women relief followed treatment directed to the exciting cause of the heart disorder.

Finally, the relation existing between pelvic diseases and mental disorders has been treated by Davenport,[5] Hobbs,[6] and Everitt.[7] Davenport thinks that physicians too often ascribe the mental condition of insane women to pelvic disease, when in reality she often finds the pelvic organs in these cases in a fairly healthy condition. [Rather than being benefited by the removal of the uterus and ovaries, it is a question whether these women are not made worse by the premature onset of the menopause. Davenport is right when she says that in the light of our present knowledge no amount of pelvic or other physical disease will cause insanity if the condition for this disorder do not exist in the brain. However, in a certain proportion of cases removal of the uterus or its appendages is beneficial, and if the pelvic disease be

[7] North-western Lancet, 1895, No. 4, p. 691.

present, the patients should be given this chance of recovery.] Everitt also states that pelvic examination of insane women in the north-western portion of the United States fails to show many or grave lesions of the sexual organs. Hobbs has noted marked mental improvement in 19 cases in which the pathologic condition was relieved by operation.

AFFECTIONS OF THE VULVA.

Kraurosis Vulvæ.—Longyear[1] objects to Tait's appellation for this disease, "serpiginous vascular degeneration," on the ground that it refers to one part only of the general process, in which a strangulation of the blood-supply occurs. He much prefers Breisky's term of kraurosis vulvæ (shrinking of the vulva), which expresses merely the general appearance of the diseased parts without attempting to describe the complicated pathologic condition. The morbid process, he believes, is due to some defective nerve-action, probably of reflex origin. All of the cases observed by him have been in women who had passed their fortieth year, and the symptoms of the disease were associated with those of the menopause. The clinical features are characteristic. The hair around the vulva is thin and dry, and late in the disease almost entirely absent; the vulva is small and infantile, the labia minora small and shrunken, and late in the disease smoothed off to almost an even surface with the labia majora; the integument is pale and bloodless, while the mucocutaneous surface is studded with a number of very sensitive, irregularly-shaped, reddish-brown spots, which on close inspection will be seen to be slightly depressed below the surface on which they lie. The parts are usually dry, and sometimes the mucous surface is cracked and abraded; occasionally a slight, brown, purulent discharge is seen. The brown spots terminate abruptly with the margin of the introitus vaginæ, being confined entirely to the vestibule. They disappear later in the disease, the mucosa becoming white and skin-like in appearance. The perineum is rigid, and cannot be retracted. Longyear adds to the pathologic features of the disease a band of fibrous tissue situated beneath the cutaneous surface, just within the vulvar orifice, but outside of the vaginal inlet. It is entirely separate from the skin and mucosa, and is an evident result of degeneration of the subcutaneous and submucous cellular tissue. He believes that the pathologic changes constituting the disease begin with this fibrous-tissue formation, and that the changes in the skin and mucosa are to a considerable extent a result of this constantly increasing condition of fibrous degeneration underlying these structures. This new formation, by replacing the loose cellular tissue through which the nutrient vessels of the skin and mucosa pass, by gradual and continual contraction results in the strangulation of the blood-vessels, and thereby produces the ecchymoses that are to be noted. To effect a cure it is necessary to eradicate the band of fibrous tissue. The operation for this purpose is made in a manner analogous to Whitehead's operation for hemorrhoids, all of the diseased mucosa containing the spots being removed *en masse*, and healthy mu-

[1] Am. Jour. Obst., Dec., 1895.

cosa from above the vaginal inlet dissected loose from its basic attachments and slipped down and sewed to the skin in its place. He recommends the entire removal of the fibrous tissue underlying the diseased mucosa.

Vulvitis.—Edwards[1] describes the condition designated by Johnstone as *trachoma of the female genital tract*, as an obliterative inflammation—a form of vulvitis. The disease cannot be traced to any venereal or microbian influence. It may occur in young or old, virgins or multiparæ. The 8 cases that have come under the author's observation have presented themselves only in a chronic form, and in three varieties, papillary, follicular, and mixed trachoma. No acute case has made itself evident. No satisfactory etiology of the disease is offered. Six of the cases referred to were in women of advanced years, a seventh in one of middle life. Bearing upon the etiology, 1 case developed immediately subsequent to a panhysterectomy, while 2 gave a distinct history of antecedent cystitis.

The clinical manifestations of the disease are very similar to those of trachomatous inflammation of the eyelid. Beginning in the region of the clitoris, it extends downward over the entire vulva, and is apt to involve the urethra and vagina. In its early stage the parts present a peculiar and characteristic appearance, not unlike the submucous or subcutaneous hemorrhage of purpura rheumatica. The surrounding tissues are apt to be anemic, but the papillæ stand up like sago grains, and a slight touch is apt to produce bleeding. After the disease has existed for a time the parts become fissured, and the thin, ichorous discharge usually present is somewhat diagnostic. Later, when diffuse scar-tissue results, it is called *trachoma deformans*. In some cases the normal contour of the vulva is obliterated, the labia minora first adhering to the larger labia and then becoming obliterated by scar-tissue, the vaginal outlet thus becoming much contracted. These cases do very poorly even under treatment. The treatment recommended is to keep the parts well cleansed with either a 5% pyrozone solution, a saturated boric acid solution, or a 20% salicylic acid solution; the parts may then be dusted over with compound stearate of zinc. As recommended by Johnstone, an ointment of yellow oxid of mercury, 4 to 10 gr. to the ounce, may be used twice a day as well.

Cumston[2] recommends tepid vaginal irrigation of about a quart of a 1 : 4000 solution of potassium permanganate, once daily, as an excellent curative remedy for vulvitis, while in nonspecific vulvovaginitis he claims excellent results from carbolated camphor (made by adding 1 part in weight of phenol to 3 parts camphor, allowing the mixture to stand 24 hours, and then filtering through gauze). Another very good preparation is a 5% watery solution of ichthyol or thiol.

The vulvovaginitis of little girls is best treated by potassium permanganate as just given, only a *rubber male catheter* should be employed instead of a glass irrigation-tube.

Herpes Pudendalis.—For this rare eruptive disease in the genital

[1] South. Calif. Pract., vol. x. No. 12, p. 447. [2] Ann. of Gyn. and Pædiat., Nov., 1895.

region Carstens[1] uses an ointment of 30 gr. of tannic acid to the ounce of cold cream, the mixture to be applied frequently during the day. Many cases seem to be of malarial origin, and in these he gives quinin and Fowler's solution.

Absorptive Power of the Vagina.—Coen and Levi[2] made a number of experiments on women with various genital diseases in pregnancy and febrile conditions, and in women whose uteri were removed by vaginal hysterectomy, as to the absorptive powers of the vagina. They obtained the following results: potassium iodid is readily absorbed; a tampon saturated with a 20% solution will give within an hour an iodin reaction to the urine. The maximum of excretion takes place in 20 hours, and in 48 hours the excretion ceases. The vaginæ of patients with fever have greater absorptive power than those of others. The same holds good of pregnant women. The vaginæ of women who have undergone hysterectomy show the same absorptive capacity as those of others. Iodoform is absorbed in very small quantities; the excretion commences in 7 hours and continues for 24 hours. To obtain a greater absorption fresh iodoform must be constantly introduced, and the first introduced left in the vagina for several days. Salicylic acid is quickly absorbed in fairly large quantities. It appears in the urine within an hour and disappears in 24 hours. Salol is quickly absorbed, and is to be detected in the urine for a long time. Antipyrin is also quickly absorbed. It appears in the urine in 1½ hours and remains for 48 hours. The antipyretic effect is less than when given by the mouth. [In general these investigations prove that the vagina has an absorptive capacity that is increased in the pregnant, the puerperal, and the febrile states.]

Vaginal Secretions in the Nonpregnant.—Menge[3] has made a series of observations as to the bactericidal properties of the vaginal secretions in nonpregnant women, and has demonstrated the fact that in 44 out of 150 women there were no pyogenic microorganisms, either at the fundus or the introitus vaginæ. He next proceeded to investigate the fate of such germs when introduced experimentally. On 35 women he made 23 experiments with bacillus pyocyaneus, 30 with staphylococcus pyogenes, and 27 with streptococcus. The result was the same in all cases: after a varying period the vagina was found to be free, and the question as to whether the vaginal secretion was acid or alkaline did not affect the result. He concludes that the germicidal process depends upon several factors that rank in order of importance as follows: (1) The antagonism between the normal bacilli of the vagina and the microorganisms that happen to penetrate there; (2) The products of the vaginal bacilli; (3) The acidity of the vaginal secretion; (4) The properties of the secretion of the anatomic elements of the vagina; (5) Leukocytosis; (6) The absence of free oxygen from the vagina. [This seems to indicate that the virulence of bacteria after parturition depends largely upon their ready access to the system through the lacerations of the birth-canal.]

[3] Lancet, Apr., 1895.

Vaginitis.—Under the name of *seborrheic vaginitis* or *vaginal seborrhea* Strassmann[1] describes a peculiar form of catarrh of the vagina frequently met with in stout women, old maids, and during pregnancy. This affection, which may be considered as simply due to an exaggeration of the normal secretion of the vagina, is characterized by a slight discharge, mainly consisting of whitish, fatty clots, in which are found agglomerations of pavement epithelium. Recovery rapidly follows vaginal injections of warm water, to which a tablespoonful of sodium bicarbonate has been added.

As a vaginal antiseptic Rolland[2] employs a powder containing eucalyptol, 1 part; thyme oil, 1 part; iodoform, 4 parts; powdered cinchona, 4 parts; boric acid, 4 parts; calcined magnesia, 4 parts. This is used after a vaginal douche of mercuric chlorid 1 : 2000. LeBlonde and Lévy[3] have experimented as to the value of a galvanic current in the cure of vaginitis. They have found that when the anode is introduced into the vagina filled with salt water, it decomposes the liquid, kills the microbes, and stimulates an abundant secretion of mucus which washes out the bacteria contained in the glands. From 5 to 13 séances given twice a week are required to effect a complete cure, the strength of the current varying between 25 and 80 milliampères. [If this be true, this affection is probably the only condition in gynecology in which electricity may be successfully and satisfactorily employed.]

[Gonorrhea in the woman is now very generally recognized as the truly serious condition that it is, and much has been written upon it.] Probably the most important paper of the year is that of Pryor,[4] in which the importance of treating the disease at the outstart, and thereby preventing its extension, is urged. For the various localizations of the disease he recommends the following treatment: *Gonorrheal urethritis* should be actively treated from the start; internally alkalinize the urine; locally apply daily a solution of silver nitrate, 10 gr. to the ounce, preferably through a slender speculum after cocain has been applied. The strength of the silver nitrate may be reduced one-half and this applied less frequently as the disease subsides. Great care should be taken lest the application reach above the sphincter vesicæ. The vulva should frequently be bathed with a $\frac{1}{2}\%$ lysol solution, but no douching is allowable. For *gonorrheal cystitis* give 75 gr. to a dram of sodium benzoate daily. Wash out the bladder with a supersaturated solution of boric acid twice daily, using large quantities and frequent flushings at each sitting. The bladder should be distended with the solution and left so. Use a single catheter for the lavage. For the *gonorrheal ureteritis* the sodium benzoate should be used internally, and the bladder washed only if it be at the same time acutely affected. The ureter may be washed out with boric acid if the bladder be not too sensitive. The urine should be rendered antiseptic, and the quantity increased by the ingestion of lithia-water in large quantities. For *gonorrheal vulvitis* paint daily every part thoroughly with a solution of silver nitrate (20 gr. to the ounce), allowing it to dry. In cases with tender

[1] N. Am. Pract., Mar., 1896.
[2] Med. Week, 1895, iii. p. 454.
[3] N. Am. Pract., Mar., 1896.
[4] Am. Gyn. and Obst. Jour., Sept., 1895.

mucosæ, as in blonds and very young women, every other day is sufficient. To prevent extension the vagina is to be packed with iodoform gauze, previously wrung out in 1 : 5000 bichlorid solution, and this must be renewed once in 3 days. The vulva should be bathed every 4 hours in a lysol-solution. The author believes in the early entire excision of the vulvovaginal glands, when infected, as the only way to permanently eradicate the disease from them. For *gonorrheal vaginitis*, the patient resting in the lithotomy position, the vagina is opened with anterior and posterior retractors, and every part of the mucosa is painted with a solution of silver nitrate (30 gr. to the ounce) and the vagina packed with gauze as before. This is repeated every other day for 2 more treatments, after which the gauze alone is used. *Gonorrheal endocervicitis* occurs 5 times as often as vaginitis. The cervical mucosa is to be touched daily with iodin on a cotton applicator passed up to the internal os, and the vagina packed as before. This treatment must be continued for many weeks. In very chronic cases it may be necessary to amputate the mucosa by Schröder's method. If caustic applications or instrumental examinations be employed, gonorrheal endometritis may follow. For *gonorrheal endometritis* operate at once after thoroughly dilating the cervix to ½ in., incising if necessary ; wash out the uterus with boric acid, then swab the cervix with 5% phenol, after which again dilate. Thoroughly curet the uterus, and wash out all débris with an irrigating catheter, using plain water only. If a strong antiseptic solution be used, a slough is produced, which acts as a culture-medium for the remaining gonococci. The uterine cavity should not be swabbed out with iodin or phenol. The uterus and the vagina are then packed with almost dry iodoform-gauze. In 5 days this is removed and only the vagina repacked. The author claims no temperature, pain, or tubal involvement as a sequence. For *gonorrheal salpingitis* (acute) the same method of treatment is to be employed as for the endometritis. Nothing but extirpation of the tube is effective if a pyosalpinx be present. [The foregoing may be accepted as a concise symposium of the accepted methods of treating the various forms of gonorrhea in the woman.]

[Janet's treatment of gonorrhea with potassium permanganate has given excellent results in the hands of many men.] In the treatment of the first stage a urethral and vesical irrigation with 1 : 1000 to 1 : 2000 solution of potassium permanganate should be made. The quantity of the solution should be a liter or more, and the treatment should be practised daily for from 10 days to 2 weeks. The discharge at first becomes more watery in character, and the gonococcus disappears after half a dozen irrigations have been made. Janet advises that the patient be watched for a week after the discharge has ceased, without treatment, and then a test of the cure be made by applying a 1% solution of silver nitrate to the urethra, and having the patient drink several glasses of beer. If the gonococcus be absent in the resultant discharge, the disease may be considered as cured. In the second stage of the disease Cumston[1] recommends a 1 : 20,000 solution of mercuric

[1] Ann. Gynæc. and Pædiat., No. 9, 1895, p. 617.

chlorid for irrigation of the bladder; in the third stage a 1% solution of ichthyol is the best preparation that can be used as an injection. The treatment of Skene's and Bartholin's glands should be accomplished by first evacuating the contents by pressure with the finger, and by means of a syringe with a suitable needle, as Anel's eye-syringe. Then a 1% solution of potassium permanganate is injected into the orifice of the gland. About 1 c.c. is a sufficient quantity. If this does not answer, the galvanocautery is advised by Janet. A 1 : 3000 or 2000 potassium permanganate solution should be used for intrauterine irrigation, and the level of the solution should be about 4 feet above the patient.

As to the diagnostic value of the gonococcus, Brewer[1] concludes that when the pus from an acute or subacute urethritis is examined by the microscope and diplococci in large numbers are found in the protoplasm of the pus-cells clustered about the nuclei, and these organisms lose their stain when treated by Roux's method, they are surely gonococci. *Roux's method* of staining is as follows: The specimen, after being spread out in a thin layer on a glass slide and heated, is treated by a solution of methyl blue, gentian violet, or fuchsin. This is subsequently washed off, and the specimen heated with Gram's iodoiodid solution, mounted, and examined. All forms of diplococci, except the gonococcus, retain their color when subjected to this process.

Vaginismus.—As regards the etiology of this affection, Gunning[2] considers it the result of pressure on, or irritation of, the spinal cord or its membranes at the end of the dorsal section and also the lumbar enlargement, with the spinal nerves; this pressure is reflected through the sympathetic nerve and by the hypogastric plexus and the pudic nerve, producing a local nervous irritation, or a neuromata of the nerves themselves, or of their peripheral ends, supplying the walls of the vagina with their fine nerve-filaments, both motor and sensory, as far as the external orifice and hymen, and also distributed to the clitoris, vagina, bladder, rectum, uterus, and ovaries. As a consequence, a low vitality of these parts exists, with poor nutrition and increased sensitiveness of the parts.

Vulvar and Vaginal Tumors.—A number of interesting cases of neoplasmata of these organs have been reported. That seen by Kidd[3] is especially noteworthy on account of its great variety. It was a case of so-called elephantiasis of the vulva (Fig. 106), in which there was no suspicion of a syphilitic origin, nor had there been previous erysipelatous attacks; the patient had never been abroad, hence the presence of the *Filaria sanguinis hominis* could be excluded. The patient was 33 years of age; she attributed the growth to a fall 13 years previously. The tumor commenced in and involved all the tissues of the right labium and hung down more than halfway to the knees. It did not grow quickly at first, but increased more rapidly in the last 18 months. There were no disorders of menstruation or micturition. The tumor was removed through an elliptic incision, and weighed, in the

[1] N. Orl. M. and S. Jour., July, 1895. [2] Am. Gynæc. and Obst. Jour., Dec., 1895.
[3] Med. Press and Circ., vol. cxii. No. 11, Mar. 11, 1896.

recent condition, 5½ lb. An examination of the growth yielded the following points: The tumor was whitish in color, covered close to the pedicle with rather dark-colored skin, from which grew a few long hairs, while elsewhere it was covered with epithelium which had the character of mucous membrane.

FIG. 106.—Elephantiasis of the vulva (Med. Press and Circ., Mar. 11, 1896).

It was lobulated and very irregular in shape, with numerous papilla-like excrescences, which caused it to resemble a gigantic wart; the consistency was rather soft. Between the larger lobes were curious sinuous cavities, some actual passages or canals running through the mass from near the pedicle at one end to the free convexity on the other. Part of the skin covering the base of the tumor was covered with innumerable small pedunculated protuberances like fungiform papillæ. Microscopically, the tumor consisted of a somewhat edematous fibrous tissue of loose texture containing so many lymph-clefts that in places one might almost term it a lymphangioma. There were also very numerous newly-formed blood-vessels. Around the lymph-clefts were many collections of lymphoid and epithelioid cells. Sections of the papilla-like protuberances showed essentially the same appearances. The surface was covered with stratified epithelium, which, from its slightly-developed horny layer and absence of hair-follicles, may be said to constitute a mucous membrane. [It is probable that this growth was a variety of molluscum fibrosum, and not a true elephantiasis.]

Cumston,[1] in speaking of primary *malignant tumors of the clitoris*, states that epithelioma of that organ usually occurs after the menopause. Former labors, trauma, syphilitic lesions, psoriasis, eczema of the vulva, and vaginal discharges are given as the predisposing causes. The affection appears in all classes of society, though it is mainly the result of poverty and vice. Its development is insidious, the patient subsequently complaining of heat and burning at the vulva; again, a pruritus vulva is often an early sign, accom-

[1] Ann. of Gynæc. and Pædiat., 1896, No. 5.

panied by more or less fetid discharge. Upon examination a tumor or an ulceration is detected—the former more frequently—which proves to be a nodular type of epithelioma. At first limited to the clitoris, the growth tends to invade the neighboring parts. The inguinal glands are sometimes involved. Simple or melanotic sarcoma, as also myxosarcoma, of the clitoris has also been occasionally met with. These sarcomata are usually rapid in growth. Neoplasms about the clitoris generally give rise, by extension, to pain and difficulty in micturition, as well as in coition and walking. The patient is usually unaware that such a condition is present until these growths have materially progressed, and it is then that the physician is first consulted. Complete excision or dissection by means of the knife and thermocautery, preferably the former, is the line of treatment advised.

[*Cystic tumors of the anterior vaginal wall*, occupying the space beneath the vesical wall, are of interest on account of their rarity. Huguier, Virchow, Guérin, Preuschen, Poupinel, and others believe that these cysts generally derive their origin from glands, and are therefore retention-cysts. Eustache, Tillaux, and Thallinger believe that they are hygromata; Veit, that they derive their origin from the terminal extremity of the Wolffian canal (Gärtner's duct); Courty thinks excessive coitus is the most frequent cause; while Cullen believes that in addition to the causes already alluded to (embryonic, traumatic, or glandular), there may be a true urethral diverticulum in which all the urethral coats take part; that they may be caused by the dilatation and possible occlusion of Skene's tubules; that they may be due to the arrest of calculi in the urethra, a diverticulum forming to accommodate the same; or that a suppurating cyst situated in the urethrovaginal junction may have burst into the urethra.]

According to Collyer,[1] these cysts may occur in any portion of the vagina, as well as in the external genitalia. Their most frequent site is found to be in the pouches of the vagina near the uterine attachment, and they are often overlooked, frequently rupturing and leaving the cyst-walls to cicatrize and form contracted bands in the vagina; these bands extend from the cervix anterolaterally, sometimes one on each side, and frequently on one side only. Naturally enough, these bands may be mistaken for probable cicatricial scars of a former rent in the vagina. The clinical history is usually unaccompanied by symptoms other than occasional inconvenience, and the accidental discovery of a bluish, semitranslucent tumor in case of a physical examination for some other condition that may have arisen. When these cysts spring from the lower and outer walls of the vagina, the attention of the patient is usually attracted by the protrusion, and, in the majority of cases, by the inconvenience experienced during coitus. The general impression in the patient's mind is that she has prolapsus, and it is of common occurrence for the physician to carelessly diagnose cysts of the anterosuperior wall of the vagina as cystocele, and those posteriorly situated as rectocele. These cysts are found singly of varying sizes and shapes. Those in the upper vagina are usually ovoid; when

[1] Am. Med.-Surg. Bull., Apr. 25, 1896.

small they are round. When found on the wall of the vagina their most frequent shape is elongated, the cysts varying in thickness and in their course of direction. The cysts found in the lower vagina seem to have thicker walls, and hence lose their characteristic bluish, semitranslucent color, and have very much the same appearance as the vagina. Fluctuation is present in all instances, but owing to the locality it is often imperceptible and deceptive. The tenseness varies in different tumors; the larger kind is less tense and compensates itself better. These cysts contain a white or straw-colored fluid, such as is ordinarily found in simple cysts. Only when they have become infected do they contain pus.

Collyer states that the positive diagnosis of cysts can always be corroborated without the least danger (if the ordinary necessary aseptic precautions are taken) by the use of the hypodermic syringe. It seems needless to state that, with cysts simulating cystocele, due care must be observed to avoid aspirating the bladder by passing directly through the cyst into that cavity. This mishap may easily be avoided by introducing a sound into the bladder to determine the relative thickness of the suspected tissue. In differentiating vaginal cysts it is necessary to classify them by positions: First, the superior uterovaginal; second, the anterior vaginal; third, the posterior vaginal; and fourth, the lateral vaginal. In the first, or *superior uterovaginal*, the cystic signs are very typical, though it is well to consider the possibility of pelvic abscess, prolapsed ovary or tube, ovarian cyst, tubal cyst, hematoma, and hematocele. Second, the *anterior vaginal:* The most frequent and usual differentiation is cystocele, urethrocele, hypertrophies, suburethral abscess, and cellular abscesses. Third, the *posterior vaginal:* In this class differentiation must be made between rectocele, varicocele, hypertrophies, and abscesses. Fourth, the *lateral vaginal:* Cysts must be differentiated from hypertrophies, vulvovaginal cysts, abscesses, cellular exudates, and the divided ends of sphincter muscles. Cysts located in the anterior vaginal wall are often richly supplied with arteries and veins, and due care must be exercised to ligate these vessels as soon as they are met with in order to prevent serious hemorrhage.

The *symptoms* of vaginal cyst are painful micturition, and, after the tumor has reached certain proportions, profuse leukorrhea and prolapse of the anterior vaginal wall, accompanied by a constant dragging pain. Two cases are reported by Wiggin,[1] 1 by Collyer,[2] and 1 by Geyl.[3] In the first of Wiggin's cases, a prostitute 26 years of age, the tumor was 3 by 2 inches, situated on the anterior vaginal wall, slightly posterior to the labia minor; it was sessile, but somewhat movable. It contained about 4 ounces of a glairy, semitransparent fluid. In the second case the tumor was found on the anterior vaginal wall, beginning at the lower margin of the meatus urinarius and extending about 1½ in.; it was 1 in. in breadth. An opening into the urethra was discovered, and the tumor could be partially emptied through this opening. It contained a brownish fluid. The cyst in Geyl's case was the size of a hen's

[1] N. Y. Med. Jour., July 13, 1895. [2] Am. Med.-Surg. Bull., Apr. 25, 1896.
[3] Centralbl. f. Gynäk., No. 44, 1894.

egg, and was found in a woman past the climacteric. It contained an opaque brownish-yellow fluid. The vaginal wall covering the cyst was not of normal structure throughout; at some points it presented a sinking-in of the superficial epithelia, forming a large irregular mass composed mainly of indifferent epithelial cells; in short, it showed a glandular formation of the vaginal epithelium. This glandular process extended deep into the cyst-wall, form-

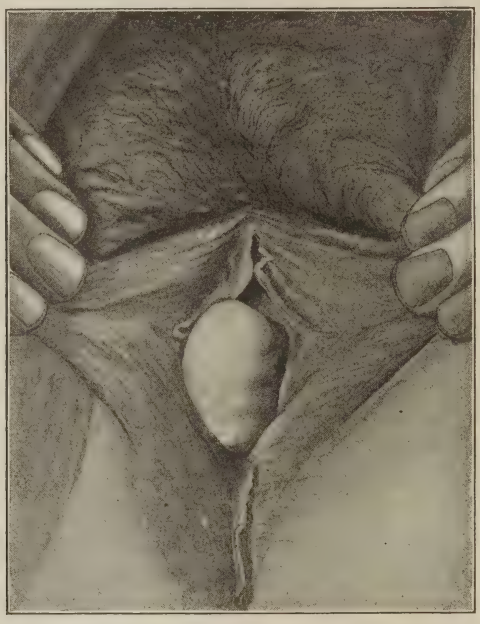

FIG. 107.—Cyst of anterior vaginal wall simulating cystocele (Am. Med.-Surg. Bull., Apr. 25, 1896).

ing similar structures. Collyer's case (Fig. 107) occurred in a German woman 36 years of age who had given birth to 2 children. The cyst resembled a cystocele, beginning on the anterior wall from below about ¼ in. back of the meatus urinarius, and extending up the vagina near the cervix, a distance of 3 in. It contained about 1½ oz. of fluid. Geyl believes that these cysts can undergo malignant changes. The treatment in all cases should be total extirpation. Turgard[1] reports 3 cases of hematic cyst, 2 vaginal and 1 vulval.

Murphy[2] reports a case of *fibroma of the vaginal wall* which was apparently attached to the wall of the urethra in the median line, and extended from that point to the left as far as the margin of the pelvis. Rectal examination showed that the tumor was about 1 in. from the cervix uteri. It was readily enucleated through a median incision in the anterior vaginal wall, and was then found to measure 9½ cm. in length and 5 cm. in diameter. It weighed 57 grams. [Kleinwächter has collected 53 cases of this growth;' Breisky adds 5 more; Hasenbalg reports 1, and Donald 1 case. Of the total number, 29 were in the anterior wall, 12 in the posterior wall, 5 in the sides, and the others not stated. The tumor may reach a considerable size; it is

[1] Ann. de la Policlinic de Lille, Feb., 1896. [2] Jour. Am. Med. Assoc., Feb., 1896.

more frequently sessile than pedunculated; its growth is very slow; it may be observed at all ages, Martin reporting a case in a child at birth, but it is most common in middle age. The symptoms are mainly due to pressure upon the bladder, urethra, and rectum.]

R. Olshausen[1] states that *primary carcinoma of the vagina* usually begins in the posterior wall. Of 18 cases coming under his observation during the past 8 years, this held good in 13 cases. From this location the disease usually extends to the cervix. In cases of vaginal carcinoma not involving the cervix he begins the operation by splitting the perineum transversely, and then dissects the vaginal wall bluntly from the rectum. In this manner an opening into the peritoneum can easily be avoided. When the uterus is involved the operation is begun in the same manner, and, after the vaginal wall is dissected from the cervix, Douglas's cavity is entered, the uterus is retroverted through the opening, the broad ligaments tied off, and finally the bladder is dissected from the anterior wall of the uterus. It is too early as yet to speak of the permanent result. Vaginal carcinoma thus far does not offer a favorable prognosis, the recurrences occurring early. In 16 of the author's cases relapses occurred in 15; in the 16th case the disease had not recurred after 2 years.

Rehn[2] advocates vaginal resection of a carcinomatous rectum, a vertical incision being made in the median line of the posterior wall of the vagina, and carried backward in the perineum as far as the external sphincter ani. This permits of free removal of a large malignant growth, and facilitates the separation of the diseased mass from the surrounding soft spots. The rectum having been plugged with antiseptic gauze and the vagina thoroughly disinfected, the posterior vaginal wall is carefully incised and separated from the diseased gut. The perineum is next incised in the middle line, and the rectum below the seat of disease isolated, ligatured, and divided. The upper and cancerous portion of the gut is now drawn through the vaginal wound and excised. This stage of the operation, it is asserted, can be effected with but little hemorrhage and with free exposure of the diseased structures. An opening in the peritoneum can be readily dealt with in this operation, and any enlarged glands in the mesorectum can be removed without difficulty.

Patency of Gärtner's Duct.—A. J. C. Skene[3] records a singular case of patency of a Gärtner's duct in a young girl of 15 years, very large and well developed, but who had all her life been greatly annoyed by a constant watery discharge from the urethra, sufficient in quantity to keep her underclothing wet all day and saturating a protecting napkin at night. The discharge was not modified in quantity by the erect or recumbent posture, nor by the empty or distended condition of the bladder. The most careful examination of all the pelvic organs revealed nothing abnormal, excepting a slight ridge or fold of mucosa in the vagina on the right side anteriorly. This elevation or ridge ran from the upper third of the urethra upward to the

[1] Centralbl. f. Gynäk., No. 1, 1895.

[2] Med. Rec., Oct. 19, 1895.

[3] Ibid., May 16, 1896.

junction of the vagina and cervix uteri. The fluid contained a very few epithelial cells and a trace of albumin, but none of the constituents of urine. A close endoscopic examination finally revealed a minute orifice from which there issued a jet of clear fluid as fine as a hair. This opening was at the place where the small ridge in the vagina joined or disappeared in the wall of the urethra. The entrance of the duct into the urethra was closed by passing a ligature around that portion of the vaginal wall (close to the urethra) which was presumed to contain the duct. This was followed by an enlargement of the vaginal ridge, confirming the diagnosis of a patent Gärtner's duct. The ridge was then divided just above the ligature and a dram or two of clear fluid escaped, after which the entire ridge was cut away; in the portion thus removed was found the duct, which was very small at the lower part, but large enough at the upper part to admit a pocket-case probe. [This is the first case of patency of Gärtner's duct opening into the urethra that is recorded in medical literature. It is also an interesting proof that Gärtner's ducts are quite distinct from the ducts of the urethral glands.]

Hydrocele of the Labium Majus.—A prolongation of peritoneum may reach below the mons veneris through the inguinal ring, covering the round ligament. This peritoneal investment may become adherent about the ring, and a transudation of serum occur into the cavity thus formed. This condition is then known as hydrocele of the labium majus. According to Edwards,[1] it may be of several varieties: 1. That in which there exists a patulous canal of Nuck. The fluid in this variety is excreted from the peritoneal surfaces covering the ligament, and is free to return within the general peritoneal cavity. 2. The sac may be entirely cut off from the abdominal cavity and dropsy occur in this closed sac. 3. The cellular tissue of the labium majus consists of two layers, which are prolongations of the superficial abdominal fascia. These 2 layers are considered the analogue of the dartos tunic, and between them a serous tumor may form. This is considered by some to be true hydrocele in woman. 4. The substance of the round ligament itself may be the site of a cyst. The gubernaculum of Hunter in the fetus becomes the round ligament in the female. This fetal structure is at first hollow, and there may be a persistence of this fetal condition which allows the formation of a cyst. Eisenhart has collated 48 cases of hydrocele in the female, and finds that 29 were upon the right side and 19 upon the left; he considers traumatism and congenital defect to be the most frequent causes. Smith believes that the disease is not so rare as is stated; during a period of 4 years he says that 5 cases have been operated upon in the Tottenham Hospital. The treatment of hydrocele feminina is operative. The cyst should be exposed by a linear incision, the neck ligated, and the cyst enucleated. The wound is to be closed by superimposed layers, as in the closure of hernia. Simple puncture of the hydrocele is of little avail.

Hermaphroditism.—An instance of male hermaphroditism is reported by Rein.[2] The subject, aged 22, died of phosphorus-poisoning. Externally,

[1] So. Cal. Pract., Dec., 1895. [2] Nouv. Arch. d'Obstét. et de Gynécol., Oct. 25, 1895.

the body presented female characteristics: the face was smooth, the breasts and hips feminine; the vulva seemed quite normal; the clitoris was about 1½ in. long; and the urethral meatus opened between the folds of the frenum of the clitoris. The labia majora were flaccid, the nymphæ well formed. On the contrary, the internal organs were male. The testes were well developed and bore rudimentary epididymises. The prostate was small and contained vesicles full of fluid. The pelvis was funnel-shaped and quite masculine.

Atresia of the Vulva and Vagina.—Coromilas[1] reports 2 cases of congenital atresia of the hymen, in 1 of which there was a large accumulation of blood constituting a hematokolpos; 250 grams of dark blood were withdrawn after puncture of the tumor. Two similar cases are reported by Webster,[2] the first patient being a girl of 18 years. The hair of the mons veneris, instead of being arranged, as is normally the case in women, with the upper limit transverse, tailed up toward the navel as in males. There was no ostium vaginæ, the hymen being fleshy and imperforate. The rectovesical examination showed but a thin partition in place of the vagina. The uterus was somewhat enlarged and only slightly movable; extending outward from it on the left side was a swelling the size of a fetal head, immovable and apparently cystic. The case was diagnosed as one of atresia of the whole vagina, with retained menstrual blood in the tubes, chiefly in the left. Abdominal section was performed and the left tube (greatly distended) and ovary were removed. The patient died of septic peritonitis 6 weeks later. Postmortem examination showed that the vagina was normally developed in its upper three-fourths and atresic only in its lower fourth. The uterus was well formed, and this was the strongest indication that the vaginal atresia was not a complete one, because Breisky claims that usually entire atresia is found only in connection with atrophy of the uterus. The case is also interesting from the fact that although the patient's history pointed to menstrual retention for about 3 years, *there was no distention of the vagina or uterus.* Breisky says that in every deep-seated atresia the distended vagina forms a large part of the retention-tumor. One of the earliest symptoms of retention may be difficulty in urination or defecation, due to the pressure of the vaginal swelling.

The rarest variety of congenital narrowing of the vagina takes the form of a transverse septum, constituting a kind of second hymen. Only about 20 of such cases are on record. Five additional cases are reported by Stone,[3] 3 occurring in young women who had never borne children or suffered injury. Pregnancy existed in each case. In the first the septum was about 2 in. from the introitus, and contained an opening about ½ in. in diameter, which admitted the tip of the finger. The membrane was elastic and thin and showed no signs of inflammation. Menstruation had always been regular up to the time of pregnancy. The second was a duplicate of the first, excepting that a few bands extended from the cervix to the membranous septum. In the third the lumen of the vagina, about 2 in. from

[1] Ann. of Gyn. and Pæd., Jan., 1896. [2] Am. Jour. of Obst., Sept., 1895.
[3] Boston M. and S. Rep., May 30, 1895.

the introitus, was distinctly narrowed by a ridge of tissue. There was uterine displacement and some endocervicitis, but no history of injury or operation and no tendency to contraction. The 2 remaining cases occurred in patients seen by Dr. J. F. Scott. In 1 the septum was about $1\frac{3}{4}$ in. from the entrance to the vagina, and contained an orifice large enough to admit a uterine probe. During labor the septum resisted the advance of the head for several hours, or until it was slit in several directions. In the other menstruation had always been irregular, the intermissions being followed by a profuse flow of black and tarry blood, which lasted sometimes for 15 days and was accompanied by severe pain. The septum was $1\frac{1}{2}$ in. from the vaginal orifice, and contained an opening which admitted a uterine sound. It was very dense and tight, and fully $\frac{1}{8}$ in. in thickness. Stone thinks that this anomaly may be explained by the following theory: The fusion of the Wolffian ducts, which form the genital tract, takes place during the third month of fetal life, and begins about two-thirds of the way down the genital tract, extending both upward and downward. The septum may be the result of fusion beginning in two places, thus leaving a band that separates the upper and the lower part of the vagina. In the fourth month the genital tract becomes flattened and the epithelial surfaces meet and grow together, forming an epithelial lamina which rapidly proliferates; the floor and roof of the vaginal tract are thrown into folds; an external thickened portion dilates and forms the ampulla of the vagina, and internally a cup-shaped outgrowth embraces the lower end of the uterus. In the sixth month the lumen of the vagina is formed by degeneration of the mass of epithelial cells. According to Tourneux's section, there are several distinct foci of degeneration, and Stone thinks it possible that groups of cells between the foci retain their vitality, and thus form the transverse septum of the vagina.

A similar case of transverse vaginal septum is reported by Chapman[1] in a young girl of 17 years, the septum being $1\frac{1}{2}$ in. within the introitus. In congenital cases it is most usual to find a partial contraction, so that the vagina presents the appearance of a funnel with the narrow end pointing upward.

Acquired contractions are most commonly the result of puerperal lesions where loss of tissue has occurred, or of instrumental labor in which the soft parts have been injured. Occasionally they may result from traumatism, the long retention of foreign bodies, or the action of caustics. Local ulcerative processes, associated with acute specific diseases or otherwise, not infrequently cause vaginal stricture. Lipinsky[2] suggests the general rule that congenital strictures occupy the upper and acquired strictures the lower portion of the vagina. Remarkable instances of acquired constriction are recorded by Hirst[3] and Hamill.[4] To effect a permanent cure in these cases recourse must be had to some form of plastic operation involving partial or complete transplantation of mucosa or skin.

Anus Vulvovaginalis.—Cases of this exceedingly interesting condition

[1] Boston M. and S. Jour., Dec. 19, 1895.
[2] Ann. de Gynéc. et de Obstét., Apr., 1895.
[3] Am. Jour. of Obst., Dec., 1895.
[4] Ibid.

are reported by Dwight[1] and Freeman.[2] The vulvovaginal anus is a very rare condition, and especially in the adult. Almost all cases reported in literature are those of infants; hence Dwight's case is of special interest, occurring as it did in the body of a white woman 32 years of age, and apparently a virgin. There was no anus, but the rectum opened into the vulva just above the posterior commissure by an orifice that would admit a large finger. The vulva was otherwise quite normal, except that the hymen was poorly developed; it consisted of merely a slight fold above and at the sides; there were no carunculæ myrtiformes. No depression or suggestion of the place of the normal anus was detected. The rectum was smaller than usual, and ran from the tip of the coccyx along the floor of the pelvis, continuing tubular to the last, without a well-marked dilatation. No sphincter could be detected at the termination of the rectum. The vagina was normal, and capacious above the entrance. The levator ani muscle was very strong. Freeman groups malformations of the rectum and anus into 4 principal kinds: 1. *Atresią ani,* in which the anus alone may be absent or the entire lower portion of the bowel as far as the upper border of the internal sphincter be obliterated. Sometimes a small fistulous opening remains, which is usually situated farther forward in the perineum than normal. A dimple often marks the spot where the anus should exist, and the fibers of the external sphincter may be present beneath the skin. 2. *Atresia ani et intestini recti,* in which the colon ends in a blind pouch at the level of the last lumbar vertebra or on the left side at the upper border of the sacrum. 3. *Atresia recti,* in which the rectum ends at some portion of its course without communicating with the anal portion of the bowel. The latter, however, is present, projecting upward from the anus like a short glove-finger. In rare cases the rectal pouch may open into the vagina. 4. *Cloaca congenita,* in which the rectal pouch, lying generally in the hollow of the sacrum, opens into some portion of the genital or urinary tract. The opening is often small, and may lead into the rectum through a narrow canal. In the male sex the opening may be into the lower portion of the bladder or into any part of the urethra, while in females it is often into the vagina, generally into the vulva near the posterior commissure (*vulvovaginal anus*). Very rarely the rectum communicates with the uterus. When the opening is in the upper part of the vagina the latter is often double, the feces passing through but one of the divisions. Between 60 and 100 cases of vulvovaginal anus have been reported. The opening is always in the posterior wall and generally low down near the posterior commissure. It may be small or large, and is usually so guarded by a sphincter muscle that fecal matter is perfectly retained, although incontinence sometimes exists. A normal anus may also be present, and the vulvovaginal opening may be closed by a membrane or by a valvular fold of mucosa, so that no fecal matter enters the vagina. Such a case was recently observed by Bernardy and Dorland in a woman over 40 years of age. In the normal condition of the bowels the feces were evacuated through the

[1] Am. Jour. Med. Sci., Apr., 1895.

[2] Med. News, Sept. 21, 1895.

anus, but when diarrhea existed there was an escape of the fluid discharges through the vaginal orifice. As regards the cure of the condition, Freeman recommends the method of Rizzoli, which is as follows: A longitudinal incision is made in the perineum from near the tip of the coccyx almost to the posterior vulval commissure. A sound is inserted into the bowel through the vaginal anus to serve as a guide, and the perineal incision is gradually deepened until the rectum is reached. This is loosened in its entire circumference from the surrounding tissues, including the posterior vaginal wall, by blunt instruments. The end of the bowel is then cut out from the posterior vaginal wall with a pair of fine scissors, leaving an opening slightly larger than the original anus, which is at once closed by fine sutures. The entire bowel, including the vaginal anus, is then swung backward through the perineal incision to its normal position in front of the coccyx, and the edges of its orifice united by a number of silk sutures to the cut edges of the skin. A few deep stitches serve to unite the perineum in front, thus restoring the parts to the normal condition. The sutures are removed on the eighth day.

Perineorrhaphy.—In writing upon kolpoperineorrhaphy Garrigues[1] states that the deep tear of the vaginal ring (ostium vaginæ), implicating the levator ani muscle and its fasciæ, is usually found backward and outward in the direction of the tuberosity of the ischium, the reason of which is probably that the muscle is caught between this point and the head, while in the median line the intervening rectum and the double fascia that descends in front of it as a continuation of the pelvic fascia furnish a soft pad that protects the muscle. The break is much more common on the right than on the left side, which probably is due to the preponderance of the first position of the vertex presentation. The occiput escapes under the rami of the left pubes and ischium, while the broad forehead continues to press in the opposite direction on the posterior wall of the vagina. For this condition of broken vaginal ring with a more or less pronounced prolapse of the posterior wall of the vagina, whether combined with a tear of the vulvar ring (*rima pudendi*) or not, Garrigues considers kolpoperineorrhaphy as the best operation. The operation consists in the removal of a triangular piece of the mucosa of the posterior wall of the vagina and the vulva, in the folding in from side to side of the denuded surface, and in the elevation of the posterior wall toward the anterior (Figs. 108–110). The operation should be performed with almost mathematical exactitude, beginning by placing certain landmarks. A point is chosen on the mucosa of either labium majus, near the edge of the same, and at such a distance from the clitoris that after the operation an opening is left of suitable size for copu-

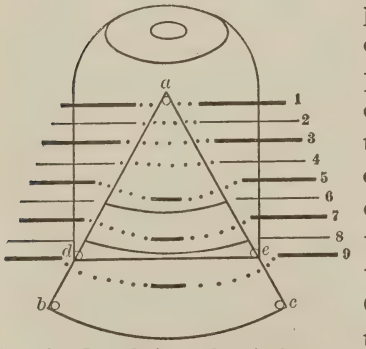

FIG. 108.—Denudation and vaginal sutures (Garrigues).

[1] Med. News, May 30, 1896.

lation. These two points (*b* and *c*) are marked by making a small nick with curved scissors in the mucosa. The labia majora are then pulled apart in a transverse direction, and the operator chooses a point in the median line of the posterior wall as high up toward the cervix as the prolapse goes (*a*),

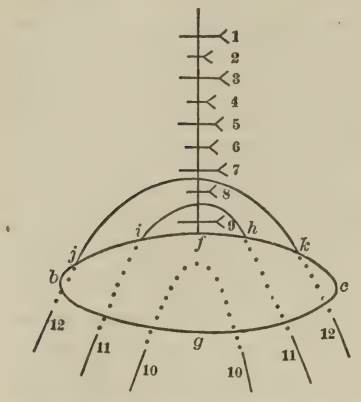

FIG. 109.—Vaginal sutures closed; perineal sutures inserted (Garrigues).

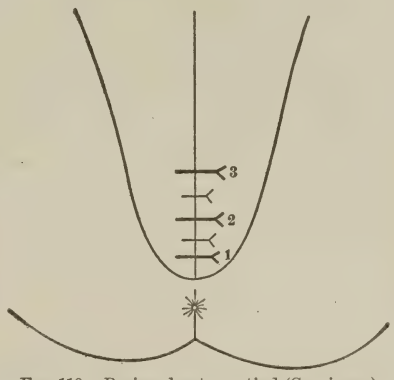

FIG. 110.—Perineal sutures tied (Garrigues).

seizes it with a bullet forceps with catch, pulls it forward and upward, putting the mucosa on the stretch, and leaves the forceps in the hands of the assistant to the left of the patient. Imaginary lines are then drawn from this point to the two nicks on the labia majora, and where these lines intersect the lateral furrow of the vagina (*d* and *e*) strong tissue forceps are inserted. A small hole is then cut in the mucosa just within the two lateral pairs of forceps, a pair of blunt scissors, curved on the flat, is introduced closed through the opening on the left side, with the concavity turned toward the operator, and pushed up to the median forceps, and then across to the other side and out through the opening there. This triangular flap is now cut loose on both sides, and the scissors is then entered through the opening on the left labium majus (*c*), and pushed up to the forceps in the lateral furrow (*e*), and down to the line of demarkation between the mucosa and the skin (*b c*), thus loosening the whole mucosa on this side. The scissors is then entered through the opening on the right side (*b*), and this half is loosened, and finally the whole piece is cut loose along the edge (*e c*, *c b*, *d e*). The second step in the operation consists in the insertion of sutures—No. 4 silk being used for the deep vaginal, braided No. 2 for the superficial vaginal, silkworm gut for the deep perineal, and fine catgut or silk for the superficial perineal. Large curved Hagedorn needles are very serviceable for all the sutures, which are inserted from side to side, beginning from the top of the triangle (*a*), alternating deep and superficial ones (1 to 9, dark lines, deep sutures; light lines, superficial), and leaving $\frac{1}{4}$ in. between two and two sutures. They are tied immediately and cut short. The superficial (2, 4, 6, 8) go only through the edges of the mucosa. The deep ones go in the upper part horizontally from side to side, and under the whole surface. When the

surface becomes too broad, the needle is brought out ¼ in. from the median line and inserted on the corresponding point on the other side. The sutures are also placed in a slanting direction (5, 7, 9), so that when tightened they lift the posterior wall up, having a resisting point behind where the lateral sulcus is yet fastened to the pelvic bones with fasciæ. Thus the stitches are inserted all the way down until the distance from the last suture to the landmark on the labia (Fig. 2, *f c*) is equal to that from the latter point to the median line, following the skin (*c g*). About 5 deep and 4 superficial sutures are needed. To form a perineum 3 sutures are inserted from the skin. The first (10) enters about ½ in. from the median line and ⅜ in. from the denuded surface, and is carried all under the surface about two-thirds of the distance up to the lower end of the closed line of sutures (*f*). The second (11) is inserted midway between the first and the third, and is brought out on the upper edge of the denuded surface, between the inner and middle third of its length (*h*), reinserted at the corresponding point of the opposite side (*i*), carried under the denuded surface and out on the skin. The third (12) is inserted outside of the outer end of the wound (*c*), carried under the denuded surface, brought out on the upper edge between the middle and outer third of its length (*k*), inserted at the corresponding point of the other side (*j*), carried under the denuded surface, and out through the skin outside of the right end of the wound (*b*). The direction given to the sutures ensures a very perfect adaptation of the edges and makes the surfaces brought in contact with one another sufficiently broad to form an excellent substitute for a perineal body. The patient is kept in bed for 2 or 3 weeks. The operation differs from Hegar's in the following points: (1) The blunt, deep denudation; (2) the slanting direction of the vaginal sutures, which lift the posterior wall up against the anterior; (3) the slanting direction of the perineal sutures, which ensures a more perfect adaptation of the edges.

CONDITIONS OF THE CERVIX UTERI.

Bacteriology of the Cervical Canal.—Stroganoff[1] has made a bacteriologic examination of the uterine cervical secretion in 31 women—11 pregnant and 20 nonpregnant. In 9 of the 11 women, 81%, the cervical canal was found sterile. The 2 remaining cases contained microorganisms, because of granular vaginitis in 1, and because a vaginal examination had been made the day before in the other. Of the 20 nonpregnant women, the cervical canal was sterile in 16—80%. The 4 remaining cases of this class he believes were infected through vaginal examination, made for 3 consecutive days for the bacteriologic examination. Cultures made the first day remained sterile; one of those made the second day contained a single colony; and of those made the third day half contained microorganisms. From his studies Stroganoff concludes that the uterine cervical canal of pregnant and nonpregnant women is, as a rule, sterile; that the area surrounding the external cervical os is the

[1] Centralbl. f. Gynäk., No. 38, 1895.

point of separation of the sterile and nonsterile female genital tract; and that the cervical mucosa destroys bacteria. He also believes that the menstrual and lochial discharges prevent infection of the uterus.

Tuberculosis.—J. D. Williams[1] reports 2 cases of tuberculous disease of the portio vaginalis. In the first case the patient was 63 years of age and the subject of pulmonary tuberculosis, from which she died a few weeks after being brought to the hospital. The genital organs, removed at the autopsy, showed a tuberculous affection of the cervix, involving a portion of the adjacent vagina. There was no tuberculous disease of the body of the uterus, nor of the appendages. In the second case the patient was 36 years of age. She showed some disease of both apices. On the cervix an irregular ulcer was to be seen, and this, on microscopic examination, proved to be of a tuberculous nature. [These cases are of interest from the location of the lesion, and because they bear out the observation made by others, that in cervical tuberculosis the body of the uterus and the appendages usually remain free of the disease.]

Congenital Erosion and Split of the Cervix Uteri.—Penrose[2] calls attention to this condition of the cervix uteri in virgin and sterile women, and which had previously been noted by Leopold in 1872 and Fischel in 1880. Fischel describes 2 distinct conditions—namely, a congenital erosion and a congenital split of the cervix, and the former is much the more frequent lesion, occurring to a greater or less degree in 36% of the infantile cervices which he examined. Penrose has had no opportunity of studying the cervices of infants, but he has met 1 undoubted case of congenital split of the cervix in a virgin, and 3 cases of disease of the cervix in young women which he thinks may be explained by the presence of the congenital erosion described by Fischel. A microscopic examination of the amputated cervix from one of these cases showed that it was covered with squamous epithelium except on the small patches of erosion on its vaginal aspect, where cylindric epithelium was present. Racemose glands (like the normal glands of the cervical canal) opened all over the face of the vaginal cervix, in front, behind, and to the sides of the external os. They were found as far as from $\frac{1}{2}$ to $\frac{3}{4}$ in. from the external os. These glands opened on the vaginal aspect of the cervix, where it was covered with squamous epithelium, and this epithelium extended to the ducts of the glands, which were lined with cylindric epithelium. The vaginal cervix was, in fact, a glandular structure. This congenital condition varies from that due to bilateral laceration with anteroposterior ectropion, in that the face of the cervix in the former condition is round, plane, or very slightly uniformly convex, and not oval, with its anteroposterior axis the longer, as in the traumatic condition. There is also no indication of any angle of laceration, macroscopically or microscopically; the cervix is mushroom-shaped, and the ectopion may be lateral as well as anteroposterior. It is probable, according to Penrose, that the condition is due to the development upon the vaginal aspect of the cervix of those structures that

[1] Brit. Med. Jour., May 4, 1895.

[2] Am. Jour. Med. Sci., May, 1896

are normally confined to the cervical canal. The proper treatment for such cases is amputation of the cervix.

FISTULÆ.

Vesicovaginal Fistula.—[Fistulæ of the vagina are becoming exceedingly rare, and in consequence the literature is annually becoming scarcer.] Probably the most important contribution is that of Schauta[1] on adherent vesicovaginal fistulæ, those in which the proximal and mesial margin of the fistula is directly continuous with cicatricial tissue intimately adherent to the descending ramus of the pubes, which forms the lateral and distal margin of the fistula. In such cases he advises vertical incision, lateral to the left labium majus; dissection down to the descending ramus of the pubes, separation of cicatricial tissue, walls of the vagina, and fistula from the bone, by means of a periosteal elevator, as far as the obturator foramen. The margins of the fistula are now freely movable, and their coaptation thereby rendered more easy. Symphysiotomy, which has been recommended by Wickhoff and others in these cases, as a rule will not give good results, since only a slight separation can be effected on account of the resistance offered by the ligamentous attachments.

Rectovaginal Fistula.—Ségond[2] reports a case of rectovaginal fistula which is remarkable alike for the manner of its causation and the method by which it was cured. The patient was a strong, healthy woman of 31. When she was a girl of 15 she and a companion each conceived the singular idea of introducing a pomatum pot into the vagina. Her companion died in a short time with symptoms of peritonitis. The patient, after much suffering, established a toleration of the foreign body, and lived in hope of its being expelled spontaneously. At 19 years of age she married without saying anything about the state of things, and until April, 1894, there seem to have been no pathologic or matrimonial troubles. Then she came under treatment with symptoms of peritonitis, rigors, vomiting, and abdominal distention and tenderness. On vaginal examination the foreign body was discovered incarcerated in the posterior culdesac and in a rent which it had made in the rectovaginal septum. This was extracted on May 3d under chloroform with careful antiseptic measures. To remove the pot it was necessary to cut off a fleshy mass that projected into its interior. A large, high-seated, rectovaginal fistula now remained, and the passage of feces per vaginam was a source of annoyance. The edges of the fistula were hard. The upper margin was formed by the indurated and ulcerated posterior lip of the cervix, which was practically continuous with the rectal mucosa. The case was difficult to operate upon. The uterus resisted downward traction and the perineum was thick and firm. After considering the exceptional difficulties of treatment Ségond operated in the following novel way: He first dilated well the sphincter ani. He then resected the anterior part of the mucosa of the rectum as far as the sphincter extended, and then separated the whole thickness of the

[1] Monatsh. f. Geburtsh. u. Gynäk., Bd. i. No. 1, 1895. [2] Ann. de Gyn., July, 1895.

rectal wall as far as the fistula. At this point he carefully dissected the rectal mucosa from the uterus. The rectal wall was now freely separated anteriorly, but still adherent posteriorly. He was able, by further careful separation, to bring down the upper edge of the fistula and to suture it to the anus. Only so much of the rectal wall was removed as was necessary for the proper proportioning of the parts. Finally, the edges of the vaginal aperture were sutured together with catgut. The patient recovered exceedingly well, and a complete cure was obtained.

Auvard[1] reports the case of a woman, 33 years of age, who had on two previous occasions been confined without the assistance of a medical man. From the time of the second confinement the patient noticed that feces passed from the vagina when she had diarrhea. She was now in labor for the third time, and delivery took place normally, the infant being alive and weighing 3600 grams. A rectovaginal fistula, admitting the tip of the index finger, was found 3 cm. above the vulvovaginal orifice. Feces came entirely from the vagina, and therefore on the eighth day of the puerperium Auvard operated on the fistula, and with complete success. The case was noteworthy in several ways: The origin of the fistula was obscure, for the labor which it followed was easy and uncomplicated, and the operation was performed on the eighth day postpartum, nearly on the day after certain manifestations of septicemia, and yet with good results.

Ureterovaginal Fistula.—Vaginal fistulæ communicating with the ureters and developing as a sequel to vaginal hysterectomy have been reported by Kelly[2] and Richelot.[3] Richelot says that they appear a week or 10 days after the hysterectomy at the time of the separation of the eschars. They are generally supposed to be due to wounds of the ureter, but he believes it more probable that they are the result of damage to the base of the bladder. Recent discussion by French surgeons developed the fact that in vaginal hysterectomy the right ureter is more frequently injured than the left. An explanation of the manner in which this accident happens is given by Fournel,[4] who believes that the right forefinger can, with little difficulty, thoroughly separate the tissue on the left side of the cervix, while the uterus is drawn down by the left hand holding the volsella, but it cannot so easily separate the cervix from the structures on the opposite side. The left hand, when grasping the volsella firmly so as to draw the uterus well down, tends to be supinated, and in that position it draws the uterus easily toward the right side of the patient; hence it becomes a simple matter to separate the tissues to the left of the cervix, working with the right forefinger, since the left hand does not readily become fatigued. To let the right forefinger work in the right side of the uterus the left hand has to be pronated, depressed toward the patient's perineum, and swung to the patient's left side; under these unfavorable conditions it is not possible to do such careful clearing away of structures, and the right

[1] Arch. de Tocol. et de Gynéc., Sept., 1895.
[2] Bull. of Johns Hopkins Hosp., vol. vi. No. 7.
[3] Gaz. méd. de Paris, Apr. 20, 1895.
[4] Gaz. des Hôp., Apr. 23, 1895.

ureter is consequently in danger when the ligatures are applied. To avoid this accident it would be well to allow a trusty assistant to hold the volsella while the operator cleans the cervix on the right side with his own right forefinger. In Kelly's case the carcinomatous degeneration of the cervix uteri invaded the surrounding tissues for a considerable distance; the ligatures were consequently placed at a greater distance than usual from the cervix uteri, and in placing them on the right side the ureter of that side was occluded. Operation for the relief of this condition was undertaken 7 weeks after the removal of the uterus. The end of the ureter could not be found on the pelvic floor, on account of the rigidity and inflammation surrounding the line of scar-tissue between the rectum and bladder. Failing to locate the ureter at this point, abdominal section was performed, when it was sought and readily found at the pelvic brim after lifting up the caput coli and incising the peritoneum and pushing aside the fat. It was then traced from the point of crossing the common iliac artery down to the pelvic floor, exposing the whole length of the pelvic portion by splitting the peritoneum over its surface. The anterior part of the ureter was involved in the inflammatory material surrounding the scar, which bled so freely that an attempt to dissect it out had to be abandoned. Finally 4 c.cm. of the tube lying directly posterior to the scar-tissue were separated from the inflammatory bed and divided close to the scar, so as to sacrifice as little of it as possible. It was found, however, that there was not enough of the tube available for union with the bladder except by making too much traction, and in order to avoid this, as the stitches would not hold under traction, the bladder was dissected free from its attachment to the horizontal rami of the pubis and allowed to drop back into the pelvis. In this manner the ureter and bladder were approximated without strain, and a small incision was made through the peritoneal coat of the bladder just large enough to receive the ureter snugly. The under surface of the ureter was then trimmed, and the union to the bladder effected by holding the ureter temporarily by a long pair of forceps introduced through the urethra, the bladder, and the incision, while 6 silk sutures were introduced through the muscular tissue of the bladder and the peritoneal and muscular coats of the ureter, beginning with the under side. The union was perfect, and a provisional gauze drain was removed from the abdomen, and the abdominal wall closed entirely after the second day. At a subsequent cystoscopic examination the newly-made ureteral orifice was found opening into the posterior hemisphere of the bladder, into which it freely discharged its urine. [There are on record 4 other cases in which during an operation the ureter was torn, and in which the ureter was reunited to the bladder: the operations were performed respectively by Novaro,[1] Penrose,[2] Krug,[3] and Baldy.[4] There are 2 others upon whom a urethro-ureteral anastomosis has been performed—Kelly[5] and Bache Emmet.[6] All of these operations were successful.]

Bumm of Bâsle[1] reports a case of ureteral fistula occurring in a woman, 30 years of age, during an instrumental delivery. Upon the introduction of the second blade the patient felt severe pain in the right side. Several days thereafter a hard mass was felt on the same side, which, as soon as the urine was passed, disappeared. There was no fever; examination disclosed a fistula of the right ureter. On account of the refusal of the patient to undergo any dangerous operation, the fistula was closed successfully through the vagina, in spite of its unfavorable position. After 8 weeks' preparation with hot injections, tampons, and daily massage, it became possible to gain access to the fistula situated in a mass of hard tissue. An attempted closure with thread-sutures caused stoppage of the flow of urine with its attendant symptoms. At first it was possible only to form an artificial vesicovaginal fistula in the neighborhood of the ureteral fistula; later the edge of the bladder was sewed to the edges of the ureteral fistula. At a third operation the vesical fistula was entirely closed. The patient was cured without any subsequent bladder-symptoms. The author recommends this method—which produced so excellent a result in an apparently very unfavorable case—for those ureterovaginal fistulæ especially that are situated high up in the vagina and are complicated by the presence of much scar-tissue in their neighborhood.

Ureteroabdominal Fistula.—Polak[2] reports an interesting case of ureteroabdominal fistula occurring in a woman upon whom an operation had been performed for multilocular ovarian cystoma. During the removal of the cyst the vesicouterine fold was torn, causing troublesome hemorrhage, which was controlled by a continuous fine silk suture. Convalescence was interrupted by a diminution in the secretion of urine during the first 96 hours, probably due to the combined action of the ether and acute digitalis-poisoning, as, through the mistake of the nurse, the patient received 62 minims of the fluid extract in 81 hours. Up to the tenth day the temperature did not rise above 100.2° F. In the next 2 days it reached as high as 103° F. Examination showed a right inguinal swelling and fluctuation. A pint of stinking pus was evacuated through an incision along the outer border of the right rectus muscle, and the cavity drained. The temperature promptly fell. It was noticed that the fluid drained from this cavity had a urinous odor, and that the quantity of urine excreted by the bladder was diminished. The existence of a ureteroabdominal fistula was demonstrated by the injection of methylene-blue and direct exploration of the right ureter. There was spontaneous closure of the ureteral fistula in 6 weeks. The patient menstruates regularly through the abdominal fistula.

URINARY ORGANS.

The Urethra.—*Stricture of the Female Urethra.*—Fischler[3] reviews the literature of this subject, and reports 4 cases occurring in 4000 dispensary patients. All 4 appeared complaining of the symptoms of vesical catarrh.

[1] Centralbl. f. Gynäk., No. 31, 1895. [2] Am. Med.-Surg. Bull., Nov. 15, 1895.
[3] Centralbl. f. Gynäk., No. 39, 1895.

Fischler believes that urethral stricture in women usually results from injury during labor or from an external traumatism. It has been observed that it may result from tumors of the urethra, as polypi, vascular and fibroid tumors, phlebectasis, carcinoma, and lupus. It is also possible that gonorrhea may be a cause, 9 cases with such an origin being reported by Herman. Fischler, however, agrees with Kleinwächter that since gonorrhea of the urethra is so very infrequently seen in every dispensary practice, and stricture so very rarely, it is scarcely to be included as a cause. Herman describes 8 cases and Kleinwächter 1 case as *senile stricture*, the patients being between 53 and 70 years of age. Herman thought that in these cases it was the result of a general fibroid thickening or induration of the urethra.

Anomalies of the Urethra.—Péan[1] reports a unique case of incontinence of urine in a young girl of 15, dependent upon the presence of a supernumerary urethra and bladder, the latter communicating with the normal bladder. As there was no sphincter at the opening of the supernumerary urethra, the incontinence could be readily explained. The removal of the additional bladder, and bringing together of the normal bladder-wall over the opening, were followed by complete relief. W. A. Edwards[2] records an anomalous condition in a nulliparous woman, 80 years of age. The opening of the urethra was at a distance of 6½ cm. from the clitoris, and situated in the median line of the anterior vaginal wall, entirely within the vulvar aperture. It was a vertical slit analogous to the male urethral opening, and was not puckered or rounded. The canal was 2½ cm. in length, and apparently traversed the bladder-wall before opening into the viscus, not unlike the course of a ureter. Careful search failed to reveal a urethra normally situated; the vestibule was smooth. [Such a case might readily result disastrously in the performance of a vaginal hysterectomy or other vaginal operation, and the possibility of urethral and ureteral anomalies should be borne in mind in all operations upon the pelvic viscera.]

The Bladder.—*Cystitis and Irritable Bladder.*—Dacheux[3] affirms that the condition of irritable bladder in women, which has previously been regarded as a purely functional derangement, is really, as Zuckerkandl states, due to a localized hyperemia of the mucosa, which can be demonstrated by the endoscope. Hyperemic patches are seen at the *bas fond*, and less often at the beginning of the urethra, which bear a close relation to concomitant congestion of the uterus and adnexa, and often disappear when the latter is relieved. In obstinate cases cystotomy is advised. Baldy's[4] experience teaches more and more that a large percentage of female patients suffering with subacute vesical symptoms, such as painful micturition, bearing-down sensations, and a feeling that the bladder is not emptied after micturition, can be readily relieved by dilatation of the urethra. The greatest amount of practical good that has been obtained in bladder-troubles by the use of the cystoscope may be attributed to the dilatation necessary to the introduction of the instrument. From

a series of cystoscopic examinations upon women suffering from pelvic diseases Kolischer[1] of Vienna has found changes to be present in nearly all cases. In cases of tumors the side of the bladder next to the tumor shows general edematous thickening. Pelvic exudate, on the other hand, produces not only local edema, but also produces a marked proliferation of the epithelium of the mucosa nearest the exudate. In young subjects troubled with incontinence there is usually found an inflammatory zone about the neck of the bladder. If this be cauterized a few times with silver nitrate, the condition will soon be cured. Cauterization of the bladder is not a painful procedure. Leder[2] reports a case of frequent micturition due to a partial retention of urine in a woman 51 years of age, which was cured by vesical massage. Ten treatments effected the cure.

Edema of the Bladder.—Kolischer[3] describes a peculiar form of edema of the vesical mucosa observed through the cystoscope. It appears in the form of circumscribed blisters the size of a pea, the rest of the membrane being normal. In some cases the blebs are so large as to resemble vesicular moles. The symptoms in this condition are painful urination, tenesmus, and a feeling of weight and pressure over the bladder. This "bullous edema" is regularly observed in connection with pelvic exudates adjacent to the bladder, especially when a pyosalpinx is adherent to that viscus. In cases of pelvic abscess in which this appearance was noted the edema and vesical symptoms disappeared after the pus was evacuated. When a solid exudate was slowly absorbed the disappearance of the edema was correspondingly tardy. It might readily be mistaken for malignant disease from the symptoms as well as from the thickening of the bladder-wall noted on palpation, but it is to be regarded as essentially of inflammatory origin. As regards local treatment, irrigation of the bladder seems only to increase the patient's sufferings. The trouble being secondary to inflammatory conditions outside of the viscus, the latter must be cured before the vesical symptoms are relieved.

Cystoscopic Examination of the Bladder.—Reynolds[4] emphasizes the importance of obtaining complete dilatation of the bladder in exploring that viscus with the cystoscope. He claims that no diagnosis can be considered satisfactory unless it be made by the inspection of a fully-dilated bladder; also, that a *negative* result derived from anything but complete dilatation is absolutely worthless. Three factors enter into the difference of results: First, and least important, in the partially dilated bladder the speculum is necessarily so near to the wall which is under examination that but a small field can be seen at any one time, and a systematic inspection of every part of the bladder is almost impossible from the loss of time involved; whereas when the bladder is dilated to its full capacity by holding the inner end of the speculum but a little inside the internal orifice of the urethra, the bladder-wall is at a considerable distance from the end of the speculum, and a large field can be covered by very slight motions of the speculum and in a short space of time. Secondly,

[1] La Sem. méd., 1895, No. 31, p. 267.
[2] Arch. de Tocol. et de Gynéc., No. 9, 1895.
[3] Centralbl. f. Gynäk., 1895, No. 27.
[4] Boston M. and S. Jour., Jan. 30, 1896.

and more important, in the partially dilated bladder there are necessarily numerous folds in which small lesions may be concealed, and, moreover, inspection of the all-important trigonal region is always rendered difficult, and sometimes impossible, by the presence of even a small quantity of urine; and it must be remembered that even if the bladder be wholly emptied at the start, the urine rapidly reaccumulates during the examination. Thirdly, and most essential, the appearance of the mucosa during partial dilatation is wholly different from its appearance when the bladder is in complete expansion. While the bladder-wall is lax, as must always be the case with partial dilatation, the mucosa has a soft, velvety-looking surface, which is rendered rough by the presence of innumerable minute wrinkles; that is, the surface looks granular; it is uniformly pink in color; granular inflammatory patches are almost indistinguishable from the surrounding healthy mucosa, and even shallow ulcerations are distinguished with the greatest difficulty. In contrast to this, in the presence of full dilatation—that is, when the bladder-walls are rendered tense by their intrinsic resistance to the expansile force of a fully-developed negative intraabdominal pressure—the normal mucosa shows a white and glistening field, over which branching blood-vessels throw a coarse network of brilliant red, and against which the smallest ulcer or inflammatory spot exhibits itself with almost startling distinctness. All folds are obliterated, and the all-important trigonal region is easily found. It seems to be a rule that if the region of the trigonum and its neighborhoods on the posterior and lateral walls are free from disease, there is every probability that the bladder as a whole is normal.

For obtaining dilatation of the bladder there is a choice of three positions: first, the position with the patient upon her back, her hips elevated by a pillow, the thighs flexed to the sides of the abdomen, and the knees extended across the chest; second, the knee-chest position; and, third, the Sims posture. The first position is rather uncomfortable for the patient, but is far more comfortable than the knee-chest posture. It renders the region of the trigonum more easily accessible than any other. It is consequently more convenient for both diagnosis and treatment, and more especially for the use of the ureteral catheter. Its disadvantages are that complete dilatation is less easily attained in this position than in either of the others, that the urine is less completely out of the way, and that a small amount makes more trouble. Kelly claims that it is better to use the knee-chest position until the patient have become well trained, and always in unfavorable cases. The knee-chest position is the most generally useful. Its great advantage is its creation of a more powerful negative abdominal pressure than can be obtained in any other, and, therefore, in the attainment of better dilatation than by any other position. The urine gravitates to the body and is wholly out of the way, so that a comparatively large amount makes no trouble. Its disadvantages are that any long maintenance of it is uncomfortable to the patient, and that the trigonal region is rather difficult of access. Sims's position is only occasionally useful. It is the most comfortable for the patient. Distention is more easily obtained than

in the dorsal position, but less easily than by the knee-chest position. It produces, however, a lateral dislocation of the bladder which is confusing to the surgeon, and makes the lower side of the trigonum and lower lateral wall somewhat inaccessible.

Contracted Bladder.—This troublesome condition, which was considered incurable until the valuable investigations of Matthews Duncan proved the contrary, was encountered by Mayo Robson[1] in a single woman, 35 years of age, who was admitted to the Leeds General Infirmary. The patient stated that her symptoms started 12 years previously, when she had great pain in the loin and at the neck of the bladder; at the same time she had to pass water very frequently, the pain and frequency of micturition having since persisted. She had occasionally passed small fragments of stone, the largest about the size of a coffee-bean. For 7 years she had had nocturnal incontinence of urine, and for 2 years complete incontinence both day and night. During the latter part of the time she had been comparatively free from pain. The urine was horribly offensive, alkaline, and loaded with pus. The patient was etherized and the pelvis examined bimanually in order to ascertain the size of the bladder, as the passage of the sound gave very little information, since immediately on entering the bladder it was arrested by coming in contact with hard calcareous material. Bimanual examination revealed the fact that there was practically no bladder, it being merely represented by a small hard lump about the size of a walnut. The ureters were apparently free from disease and there was no enlargement of the kidney. The urethra was dilated by a Weiss's dilator so as to admit the little finger, when it was found that the minute cavity was lined by phosphatic concretions, which were thoroughly scraped away by a Volkmann's spoon, the bladder then having a capacity of only ½ oz., and, although the patient was under an anesthetic, no more could be injected by any reasonable amount of force. The incontinence persisted after the operation, and the bladder was washed out daily with boracic lotion, on each occasion the urethra being compressed around the nozzle of the syringe and moderate force being used in order to increase the capacity of the organ. After a few days the incontinence ceased, and the patient was told to hold her urine as long as possible. One week later she could hold it for half an hour. Twelve days later, as the patient had made no further progress, ether was given and the bladder distended with boracic lotion, when it was found that the capacity had increased to 2 oz. In 6 days considerable improvement had taken place, as she was able to retain her urine for 3 hours with some effort, and the quantity retained was 4 oz. Nine days later she held her urine for 4 hours. The bladder was again somewhat forcibly distended, but without an anesthetic; the capacity, however, could not be increased beyond 4 oz., and the next day the patient had pain in the hypogastrium with vomiting and considerable irritability of the bladder. This decidedly retarded progress, and, although in 3 weeks' time the capacity of the bladder was found to be still 4 ounces, there was very frequent micturition

[1] Ann. of Gyn. and Pæd., Feb., 1896.

and a slight elevation of temperature. Further dilatation was therefore not attempted, as it was thought that, the bladder having now some capacity, voluntary retention of urine would secure gradual dilatation, and this proved to be the case, for in 2 weeks' time she was able to retain 7 oz. of urine. Up to this time the patient had been kept in the recumbent posture, as it was found that she could thus hold the urine much better. In 2 more weeks her general condition was very much better than it had been for years, and the voluntary power of retention was good. In another fortnight she was able to hold 7 oz. of urine even when up and about, and she had not to micturate for 5 hours; and 10 days later she was discharged; she could hold 8 oz. of urine without discomfort and her general health was good and the urine normal. [This is practically the method of treatment as recommended by Duncan.]

Urinary Analysis.—[The value of a close observation of the condition of the urine in gynecologic cases is now much more generally appreciated than was formerly the case. Not only is this true of postoperative cases, but of nonoperative cases as well.] Probably the most important papers of the year on this subject are those of Etheridge[1] and Bloom.[2] Etheridge remarks that if the solids are excreted in sufficient quantity a normal condition exists. If they fall short of it, say 20%, an insufficient quantity is excreted and a true renal insufficiency exists. The amount of solids voided by healthy human beings may be assumed to vary from 500 to 1100 gr. daily, according to body-weight. Thus, a woman weighing 90 lb. ought to pass 500 gr., and a woman weighing 180 lb. ought to excrete 1100 gr. of urinary solids. With this knowledge to work from it is an easy matter to estimate the amount of solids that women of intermediate weights should void. Various working formulas exist for estimating solids; that recommended by Etheridge is known as Haines's modification of Haeser's method. Its simplicity and speedy solution relieve it of all the objections belonging to formulæ relating exclusively to estimating urea. It is this: Multiply the last two figures of the specific gravity of the urine by the number of ounces voided in 24 hours, and the product by $1\frac{1}{10}$. Thus, if the amount of urine voided in 24 hours be 36 oz. and its specific gravity be 1021, the formula would read 36 times 21 times $1\frac{1}{10}$ equals 831, the number of grains of solids contained therein, including urea and all the other solids. Etheridge has had an expert physiologist construct the following table, showing the amount in grains of normal excretion of urinary solids of human beings weighing from 90 to 180 lb.:

Weight.	Urinary solids.	Weight.	Urinary solids.
40 lb.	392 gr.	130 lb.	1028 gr.
50 "	479 "	140 "	1078 "
60 "	563 "	150 "	1150 "
70 "	639 "	160 "	1198 "
80 "	716 "	170 "	1237 "
90 "	789 "	180 "	1260 "
100 "	854 "	190 "	1300 "
110 "	916 "	200 "	1330 "
120 "	974 "		

[1] Chicago Med. Recorder, July, 1895.

[2] Univ. Med. Mag., Dec., 1895.

Women passing only 50% of the normal amount of urinary solids are extremely numerous. Women passing not to exceed 400 gr. of solids daily present varying degrees of nervous irritability. When the amount is lessened to 300 gr. or less daily, the condition of nervousness becomes a very serious semeiologic factor. Let a patient passing this amount of solids take a severe cold and she will develop a bronchitis, or a severe neuralgia, or a fresh attack of perimetritis, or a pleurisy, or some other malady equally grave. When the solids are diminished to 200 gr. in 24 hours the nervous system becomes very seriously invaded; and with the amount still further diminished, say to 100 gr. per diem, the patient will be found dangerously near the verge of uremic convulsions, the condition not infrequently found in the last weeks of gestation. Bloom emphasizes the importance of urinary analysis in gynecology, and gives the statistics of 1000 cases, largely taken from the records of the Gynecean Hospital in the service of Drs. Baldy and Penrose. In 11%, or 110 instances, albumin was found. The urine was acid in 75% of the cases. The specific gravity averaged between 1025 and 1030. In 25% the albuminous urine contained casts, the forms predominating being the granular and hyaline. In 75% of the remaining analyses in which albumin was present the albumin depended upon the presence of pus, associated with cystitis. In 1 case hyaline casts were found, but the urine was not albuminous. In 1% of the cases sugar was found; lithuria, oxaluria, phosphaturia, and indicanuria were frequently noted.

The Kidneys.—The Diagnosis of Ureteral and Renal Disease.—In some remarks on some of Pawlik's methods of investigation that he has been engaged in developing during the past year, Kelly[1] considers the following three methods of diagnosis: 1. Inspection; 2. Catheterization of the ureter; 3. Catheterization of the pelvis of the kidney.

1. *Inspection.*—In the ordinary examination without incision inspection is limited to the ureteral orifices in the bladder. The method adopted is the following: The patient is asked to urinate. She is then placed in the knee-chest position and a 10% cocain solution is applied to and within the external urethral orifice for 5 minutes. The urethra is dilated, when necessary, with a single conical dilator, up to 9 or 10 mm. in diameter. A simple cylindric vesical speculum, provided with an obturator, is next introduced into the bladder and the obturator withdrawn, when the bladder at once balloons with air. The examiner, with a head-mirror on his forehead, now reflects into the bladder a light (preferably electric) held as near the sacrum as possible. By turning the speculum 30° to the right or left and dropping the handle the ureteral orifice comes into view. The inspection is limited to this area, and three points are to be noted: (*a*) The appearance of the orifice and its surroundings. In inflammatory disease of the ureter or kidney this is often red, edematous, puffed out, mammillated, or even slightly ulcerated. In tuberculous disease descending from the kidney the author has seen the infection thickly strewn over a triangular area, the apex of which was at the orifice. (*b*) The charac-

[1] Internat. Jour. of Surg., June, 1895.

ter of the fluid seen issuing from the orifice will often settle the diagnosis and determine the plan of treatment. In cases of hematuria, pyoureter, and pyelonephritis there is no difficulty in locating the affected side, and seeing by the clear urine issuing from the other side that it is sound. When no discharge takes place it may sometimes be started by making bimanual pressure upon the renal tumor. (*c*) Normally, the urine flows in intermittent jets of a clear, limpid fluid. If one side discharges in this way and nothing comes from the other, there must be some obstructive disease. Pus-accumulations, when they escape, are likely to flow in a continuous sluggish stream. Attention is called to the fact that it is possible to catch the urine, as it escapes, directly in the speculum, and take it up for microscopic, chemic, and bacteriologic examination without passing a catheter into the ureter.

2. *Catheterization of the Ureter.*—In carrying out this procedure strict attention must be paid to antiseptic details. The method is as follows: An antiseptic speculum is employed. The ureteral orifice is cleansed with a pledget of cotton held in mouse-tooth forceps. A sterile catheter, not contaminated by handling nor soiled during the introduction, is passed into the ureteral orifice. The sterile outer end (protected up to this time with a piece of rubber tubing) is placed in a test-tube to collect, without contamination, the urine as it flows from the ureter. Kelly uses three varieties of catheters. That which he prefers is a flexible silk catheter, 30 cm. long and 2 mm. in diameter, with a blunt conical end and a large oval eye 2 cm. back of the extremity. In introducing the catheter it is engaged in the orifice of the ureter and pushed in for a distance of 12 or 15 cm. It may be left there as long as desirable. He also uses a simple, straight metallic catheter, which, however, is more liable to bruise the ureter, and a short metallic catheter, which is introduced entirely within the bladder and ureter and discharges through a fine rubber tube. Both ureters may be drained easily at one time with the flexible catheters. By noting the time the catheter is put in place and removed the rate of flow may be determined, and by the examination of the urine the relative value of the two kidneys is determined.

3. *Catheterization of the Kidney.*—For this the author has had made renal catheters 50 cm. long and $1\frac{3}{4}$ to $2\frac{1}{2}$ mm. in diameter, which are kept sterilized in glass tubing, and when introduced are simply drawn out of the tubing as they are pushed into the ureter. In this way he has drawn pus from the kidney, evacuating a large renal abscess, and by irrigating the abscess-cavity he has relieved a pyonephrosis.

As regards the diagnosis of *renal calculus* in women, Kelly[1] says that the presence of pus in the urine is one of the most characteristic signs of calculus in the pelvis of the kidney, but from the mixed urine in the bladder it is impossible to say from which side the pus comes; or if pain and swelling point distinctly to one side, it cannot be asserted, after any ordinary examination, that the other side is not affected too. To overcome this difficulty he passes the renal catheter as far as it can go. Usually 13 to 17 cm. of the

[1] Med. News, No. 1194, p. 593.

catheter are left projecting from the ureter. An airtight syringe with a tapering point is then connected by means of a fine rubber tubing with the end of the catheter, and separate suction is exercised. If pus be present, it is brought down at once into the syringe, and begins to flow long before it would naturally without suction. Suction is continued until the renal pelvis be emptied, and the fluid obtained is placed in a conical graduate for examination. In 3 cases he has been able to diagnosticate the presence of renal calculi by discovering in this fluid a minute dark-brown or black sediment consisting of small pieces of material about $\frac{1}{2}$ mm. or less in diameter. Under the microscope these were found to be composed of uric acid. Their appearance on the surface was mammillated, looking like an aggregation of little masses of rounded stone. On pressing them with a needle-point they were found to be quite coherent, each separate particle bending and breaking under pressure. In another case a small piece of stone was caught in the eye of the catheter and scratches were found on its end. Kelly has also devised a hard-rubber renal bougie, 2 mm. in diameter, with an olive point 3×2 mm., notched on two sides, the notch running lengthwise; some dental wax is melted, so as to coat the end of the bougie, giving it a smooth, glossy, impressionable point, which is not altered by any kind of contact with the soft tissues, but is easily scratched by the stone. By the foregoing methods the following points are claimed: 1. By renal catheters to demonstrate a unilateral or a bilateral pyelitis and the grade of each. 2. By suction at the outer end of the catheter to bring down bits of stone for microscopic and microchemic examination. 3. The color of these pieces of stone will denote the length of retention in the pelvis of the kidney. 4. The bruised end of the catheter is macroscopic evidence of violent contact with a hard body. [It is well to bear in mind that it is only in picked cases that the catheter can be passed into the pelvis of the kidney, and when it does succeed in passing the amount of good thus far accomplished has been practically *nil.* It is not difficult to imagine the amount of harm that might result from indiscreet and persistent efforts in this direction. One case of pyonephrosis was reported cured by the treatment, but it is our impression that at a subsequent time it was found necessary to remove the kidney.]

MENSTRUATION AND ITS DISORDERS.

The Period of Puberty.—[There has been noted within recent years a marked tendency to a more systematic supervision of the age of puberty in girls in an effort to overcome the proclivity to the development of sexual disorders that is characteristic of this critical period of their lives.] In the line of this evolution mention must be made of the paper of Playfair[1] upon the education and training of girls of the easy classes at and about this period. He insists that there should especially be borne in mind the highly sensitive nervous organization of the human female, the development of the emotional element that distinguishes the woman from the man and influences the cha-

[1] Brit. Med. Jour., Dec. 7, 1895.

racter and progress of all kinds of disease in women, but much more especially the diseases of the reproductive organs. He urges that the attention given to exercise and athletics in girls' schools is not nearly sufficient. It would not be difficult to make games compulsory, as they are in public schools for boys, and there are some that are admirably adapted for women, as, for example, golf, or rowing when it is feasible, or it may be bicycling. Each of these pastimes exercises the muscles generally, without those spasmodic efforts required in cricket, football, or even lawn tennis, which are, perhaps, too violent for girls. One other regulation in girls' schools he would like to see made compulsory, and that is that no form of corset should be worn.

[The subject of *bicycling for women* is beginning to attract the attention of medical writers.] Hogg[1] gives the opinions of a number of French, English, Belgian, Spanish, Holland, and Swiss gynecologists as to whether bicycling is beneficial or not to the health of women. The greater number agree, as Auvard, Chaput, Doléris, Treub, and Vulliet, that, as a rule, where it is not carried to excess, in women with healthy genitalia it is a profitable exercise; while a few others, among them Tait, condemn bicycling for women. The harmful influences which this exercise has are dependent upon its being overdone, the general health suffering, or upon faulty position and imperfect construction of the saddle, local diseases being produced. Women who have chronic inflammatory disease of the genital organs should not be allowed to ride a bicycle, since it causes hyperemia of these parts and thus accelerates the disease. A large number of French and other gynecologists believe that bicycling is a healing factor in disturbances of nutrition, as neurasthenia, hysteria, chlorosis, dyspepsia, and the like; also in chronic constipation, anemic amenorrhea, and nervous dysmenorrhea.

Townsend and Chadwick[2] have instituted a similar investigation among a number of female physicians of Boston. All but one stated decidedly that they considered bicycling of value to the average woman, some giving the qualifications that the wheel should be used in moderation, both as to length of ride and speed, and that the proper dress and posture should be observed. In uterine disease the majority limited the exercise to chronic cases, especially when the circulation was sluggish and the muscular system relaxed; cases of uterine neurasthenia, dysmenorrhea, amenorrhea, chlorosis, moderate displacements, and imperfect development are especially suitable for this form of out-of-door exercise. These favorable criticisms were not obtained from bicycling enthusiasts, as only 1 of the physicians consulted had used a bicycle herself.

Chadwick states that as yet no effort has been made to adapt the saddle to a woman's anatomy. The bicycle saddle for men seems to have been modelled upon the saddle that was found suitable for men riding upon a horse, being merely reduced in most of its dimensions. This has answered most of the requirements, though it has often been found to strike against the prostate gland or the pubic arch. When women began to ride they were given the same saddle, regardless of the fact that behind the pubic bones are the external genital

[1] Province méd., No. 38, 1894. [2] Boston M. and S. Jour., cxxxii. No. 24, 1895.

organs, so prominent as inevitably to rest upon the anterior projection of the saddle. The result has been that women have generally had great difficulty in having the saddle so adjusted as to be rendered comfortable; in other words, to avoid pressing unduly upon the vulva. To overcome this difficulty several alterations become necessary. In the first place, a woman's pelvis is broader than a man's, and the tuberosities of the ischia are farther apart in woman than in man; consequently, the width of the rear portion of the seat needs to be greater. Secondly, the anterior projection of the saddle must be tilted downward so that it will not strike against the vulva. This, however, requires the most delicate adjustment, for if the saddle is tilted too far the slope of the seat causes the rider to slide forward, so as to rest almost entirely upon the anterior projection, and so defeat the object of the tilting. Again, the seat may be shifted backward and forward upon the frame without tilting. When shifted backward the action of the leg upon the treadle tends to push the body backward, and thus to ensure that the ischia shall rest upon the saddle; but in this location the muscular action of the legs is less effective, which renders the work of propulsion greater.

Dickinson[1] states that 9 out of every 10 bicyclists are ignorant of some of the rules of good riding, and that unmerited disrepute is thus thrown on the most alluring and practicable, as well as the most generally beneficial, of the outdoor exercises for women. He lays stress on a careful increase of length and difficulty of the ride; on heeding the warning given by palpitation and labored breathing—signs of strain of the right heart, which is only robust in laborers and athletes; on frequent rests; on care about chilling and over-fatigue; on light food during exercise; and on rest after riding. Saddles must differ as pelvic floors, as buttock contours, and as thigh modellings differ. A narrow saddle, permitting the wide pubic angle to straddle it, will bring weight on the vulva, and a saddle tilted downward in front will slide the trunk forward on to the narrower portion of the saddle. Dickinson claims that investigation proves sexual feeling not to be aroused or self-abuse fostered by wheeling. The scorching position is the only attitude in which the pubic arch is likely to span the front pommel or the vulva to come in full contact with the saddle. Some of the injurious and not uncommon defects in saddles are—a center ridge; sagging, or the hammock-shape; narrowness; and a vicious tilt. The available types of saddle he roughly classifies as follows: First, the narrow man's saddle, suitable to a few women; second, the most commonly used and most useful of all, the modified male type of the shorter, broader, flatter form, supplied with most wheels on request. It should not be less than 8 inches wide. As examples are the Mesinger, Garford, Hunt, and Reform Wheeler. There is the saddle with the pad on each side to carry the weight, with a deep groove in the center and without front pommel. Of these the best is the Christy. Many people find comfort and relief to perineal pressure in this seat. It is less secure than the usual form, and chafes some riders. Doolittle[2] says that in cases of pus-tubes, of acute inflammation,

[1] Am. Gynæc. and Obst. Jour., June, 1896.

[2] Canad. Pract., May, 1896.

or immediately following inflammation with exudations—in fact, in any condition in which pelvic massage would be contraindicated—the use of the bicycle should be proscribed. It is, however, of service in subacute metritis or in subinvolution, and in pseudohysteric cases of uterine origin.

[There are but two possible objections to bicycle-riding in women. The one, over-exertion, should be and is easily controlled; the other, pressure on the vulva and its results, is entirely eliminated by the use of the Christy or some similarly devised saddle. Bicycle-riding can do no possible harm to a healthy woman, any more than it can to a man, unless it be abused. For neurasthenics in particular it is an exceedingly valuable remedy—probably the most valuable we have.]

The Phenomena of Menstruation.—Joubert[1] from a careful study of the supposed influence of tropical climate on menstruation, based upon over 3000 patients between the ages of 10 and 19 years, arrives at the conclusion that the reason why girls in tropical countries menstruate at a relatively earlier age than Europeans is not the influence of the climate, but of too early sexual excitement, the direct result of the social life of these people, in whom very early marriages are the rule. Kisch[2] notes the following phenomena in connection with the establishment of the menstrual function: 1. Palpitation and tachycardia in individuals otherwise healthy, appearing before the first menstrual discharge and persisting for some time afterward; 2. Cardiac irregularity in chlorotic females; 3. Hypertrophy of the heart, which develops at the time of maturity, caused by the circulatory disturbance which then occurs, as well as by the rapid growth of girls and improper habits of dress. Van Meerdervoort,[3] from a study of uteri removed during menstruation, concludes that in consequence of vasomotor dilatation of the pelvic vessels the cervical and corporeal endometrium becomes intensely congested, resulting in a transudation of blood, as well as in an increased secretion of mucus. When the congestion and resulting serous infiltration are moderate, corresponding to a condition of slight capillary congestion, the menstrual flow is slight, and the reverse. The degree of congestion depends upon the intensity of the ovarian stimulus.

Depasse[4] says that cold bathing during menstruation is a beneficial measure, provided women accustom themselves to the treatment by bathing every day for at least 8 days before the arrival of the period, when they can continue during the menstrual flow without any danger. In the case of a very anemic girl, in whom this treatment was instituted, it gave most satisfactory results. Houzel, before the recent Boulogne Congress, held that cold salt-water baths facilitate the menstrual flow, increase the duration of genital life, and likewise increase fecundity in a remarkable manner.

Precocious Menstruation.—E. G. Woodruff[5] records the following interesting case of unusually early menstruation, which he was able to see and

[5] Med. Rec., Mar. 7, 1896.

examine through the kindness of Prof. A. Monti at the Policlinic in Vienna on Jan. 23d. The face and general appearance were those of a well-developed girl of 14 or 15 years of age. The child is of the brunet type, and stands 118 cm. in height. The chest measure is 72 cm., and that of the pelvis with the pelvimeter is as follows: At the crest of the ilium, 20 cm.; at the anterior superior spine, 21 cm.; and at the great trochanter, 25 cm. Upon inspection the breasts were found to be full, firm, and round. The mons veneris was covered with hair. The hymen was present, and the uterus was found on rectal examination to be normal. According to the statements of the mother, the child began to menstruate at the age of 2 years, and has done so regularly since, the flow being normal in amount. Menstruation appeared as usual between the twelfth and fourteenth years in the mother and five sisters of the child. The general health of the child seems up to the present time to be undisturbed in any way by this menstrual precocity.

Vicarious Menstruation.—Kutner,[1] in a study of vicarious menstruation, states that bleeding from the stomach is much more frequent than vomiting of blood, but it can only be diagnosed by examination of the feces. The hemorrhage often comes on periodically in connection with menstruation, or, more frequently, at the menstrual epoch in patients suffering from amenorrhea. Hemorrhage from an ulcer of the stomach is also frequently dependent upon a menstrual period. The differential diagnosis between an ulcer of the stomach and menstrual hemorrhage from the stomach is by no means easy, and in some cases it can only be made out by resorting to a prolonged rest-cure. Want of success will indicate that no ulcer is present.

Amenorrhea and Chlorosis.—Clement[2] affirms his belief in the infectious origin of chlorosis, founding his opinion on the similarity between this and other infectious diseases. He observed an epidemic form in a small village, in which 8 young girls under favorable hygienic conditions were successively affected, fever being the initial symptom. Enlargement of the spleen was constant, phlegmasia alba dolens, dry pericarditis, and pleurisy being frequent complications. These could hardly be explained by a simple disturbance of the hematopoietic function. [This cannot be accepted as a probable explanation of this common condition, which is of such frequent occurrence that its specific cause, if it were infectious in nature, would have been demonstrated long ere this. It is probably only another instance of the general tendency of the day to ascribe all diseases to a specific virus. It is much more rational to attribute the disease to a profound anemia consequent upon the rapid growth and development of the girls at this period of their lives, together with an associated alteration in the body-metabolism.]

In the treatment of amenorrhea Lutaud[3] recommends gymnastic exercises, hydrotherapy, sea-bathing, and saline spring baths. When the amenorrhea is accompanied by obesity, active purgation must often be employed, and this increased at the approach of the period. In obstinate cases success has

[1] Berl. klin. Woch., 1895, Nos. 7–9. [2] Centralbl. f. Gynäk., 1895, No. 40.
[3] Therap. Gaz., Nov. 15, 1895.

attended the use of *Mempanthis trifoliata*. This is given in infusion, made by adding 1 oz. of the drug to 6 oz. of boiling water, macerating it over night, and is taken in small quantities during the next few days.

Menorrhagia and Metrorrhagia.—As to the origin of excessive menstrual and intermenstrual discharges, Bloom[1] states that they can nearly always be traced to chronic endometritis, subinvolution, pressure of submucous fibromyomata or other uterine neoplasms, malignant disease of the uterus, or faulty positions of this organ. The ovarian and tubal origin of these hemorrhages must not be overlooked. In all cases of organic disease of these structures there is an associated endometritis that gives rise to the repeated bleedings. Bloom has studied upward of 500 cases of excessive bleeding, either menstrual or intermenstrual, observed in the Gynecean Hospital in the services of Drs. Penrose and Baldy. Ten % or 50 women, showed no pathologic condition from a physical examination. Carcinoma and suspected malignant disease of the uterus accounted for 5 %, or 25 cases. Fifteen of these women came under hospital observation; 7 were too far advanced for extirpation; in 8 hysterectomy was the operation selected; and in all cases the diagnosis was verified by microscopic examination. The average age in these women was 41 years 3 months, the oldest being 63 years of age, and the youngest, an African, of but 28 years and a hopeless case. They were all multiparæ, and the average number of pregnancies was 4½. Tuboovarian disease represented the cause of bleeding in 20 %, or 100 of the cases. There were 2 cases of extrauterine disease that gave histories of profuse bleeding. In 10 %, or 50 cases, faulty positions were responsible for the excessive bleeding, and of this number fully 80 % were retrodisplacements. In the remaining cases, or nearly 45 %, the bleeding was traceable to an endometritis or subinvolution.

Sivitalski[2] calls attention to the rare occurrence of metrorrhagia without any discoverable local or general cause, and states that he regards this condition as a clear indication for total extirpation. He reports the case of a woman, aged 29 years, who began to have profuse metrorrhagia a week after the cessation of the menstrual flow. The same phenomenon was noted after the following period, when the patient became so exsanguinated that she entered the hospital. The removal of a quantity of hypertrophied mucous membrane by curettage failed to check the bleeding, which recurred a few weeks later and could not be controlled. She was readmitted to the hospital, and a digital examination of the uterine cavity was made with a negative result. It was finally decided to perform hysterectomy, for the patient was *in extremis*. A careful examination of the specimen threw absolutely no light upon the cause of the hemorrhage, as the only pathologic change noted was a minor degree of interstitial endometritis. The adnexa were normal. The patient developed a pelvic abscess, but eventually made a good recovery.

Steam as a hemostatic in cases of uterine hemorrhage has been claiming of late a considerable amount of attention. Zacharine,[3] Snegirjoff,[4] and

[1] Codex Medicus, Feb., 1896.
[2] Centralbl. f. Gynäk., 1895, No. 33.
[3] Rev. de Thér., 1894, No. 22, p. 626.
[4] Centralbl. f. Gynäk., 1895, No. 3.

Pincus,[1] all endorse the method as of undoubted value, particularly from a bacteriologic standpoint. Pincus recommends it in septic puerperal endometritis. For the last 7 years Snegirjoff has employed this method after dilatation and curetment of the uterine cavity. A small metal cannula attached by a rubber tube to a kettle containing water at the boiling-point is introduced into the cervical canal and the steam applied for 1 minute. It is always followed immediately by complete hemostasis, and is not associated with pain or other symptoms. Applied in carcinoma of the uterus, the fetid discharge and hemorrhage disappear and the pain is relieved. Experimentally applied to the uterine cavity of an extirpated uterus, the endometrium was found to be cauterized, and was covered with a thin white membrane. Thus, the steam acts as a cauterizant, hemostatic, anesthetic, and antiseptic. Prompted by these observations, Snegirjoff, with the assistance of Blagowolinof, carried out a series of experiments on animals with the following results: The liver was extirpated with the loss of but little blood, the animal living; also a portion of the spleen, lung, kidney, and brain. Hemorrhage from bone was controlled, a new growth of bone-tissue following the operation. A horn of the uterus of a dog was excised. Bleeding from a longitudinal or transverse incision in the femoral artery ceased after the application. Hemorrhage from muscle or skin ceased immediately. The operation was always followed by primary union. After this experimentation Snegirjoff began, in 1893, to apply the method in a series of operations at the Alexinas Hospital. In 5 cases of resection of the knee-joint the operation was performed without the use of an Esmarch tube, hemostatic forceps, or ligature; also in amputation of the breast for carcinoma, and in carcinoma, lipoma, and cavernous tumors of the skin, in the amputation of the cervix, in the operation of hysterectomy for fibroid tumors, and to control hemorrhage from the stump. After the incision of abscesses as a method of disinfection, and in hemorrhage from a sinus or fistula, particularly if the latter was tubercular, hemorrhage was controlled entirely by the use of steam in the manner described. Pincus[2] reports 9 cases in which steam was employed in controlling hemorrhage from the uterine cavity and in treating endometritis. [This remedy is worthy of additional investigation as to its antiseptic and hemostatic properties.]

Among the new remedies that have been recently employed to control uterine hemorrhage may be mentioned calcium chlorid[3] in the form of liquor calcii chloridi (B. P.) in from 2- to 3-dram doses. The strength of this preparation is 1 dram of the calcium chlorid to 5 of water. Its action is due to the fact that the blood coagulates much more readily under its influence.

Orthmann[4] has employed salipyrin as a hemostatic for uterine hemorrhage in 50 cases at the Martin Polyclinic. He reports 32 cases in which the patients were under observation for from 9 to 18 months. In 12 of these there was no positive improvement, in 12 others distinct improvement, and in 8 the result was very good. The best results were obtained in those cases of men-

[1] Centralbl. f. Gynäk., 1895, No. 11.
[2] Loc. cit.
[3] Routh, in Clin. Jour., Dec. 18, 1895.
[4] Berl. klin. Woch., No. 7, 1895.

orrhagia that follow labor and abortion. Those complaining of severe menstrual hemorrhage associated with pain were undoubtedly relieved. In 2 of these cases of menorrhagia with disease of the uterine appendages the result was good. In 4 cases of associated metritis, perimetritis, and oophoritis there was no apparent change, and the remedy was also of little or no use in 7 cases of uterine hemorrhage following salpingo-oophorotomy. Orthmann advises that salipyrin should be administered, if possible, for 1 or 2 days before the expected appearance of menstruation, and that it should be continued until the flow ceases. The dose advised is 15 gr. 3 times daily. He believes that further experimentation is desirable.

Schaeffer[1] recommends ferripyrin: (1) as a simple hemostatic in all forms of hemorrhage from the genitals in which cauterization is not desired; in menorrhagia and metrorrhagia; and in operations associated with parenchymatous hemorrhage when ligature is impossible; also in cases of endometritis when destruction of the superficial endometrium is required, and after curetment in those cases suitable for the application of ferric chlorid. It is here applied in a 16 to 18% watery solution with an intrauterine applicator. (2) As a hemostatic when an associated astringent quality is desired; in intrauterine and vaginal douches, as in endometritis, to control the hemorrhage and to act as a stimulant to the endometrium; also in metritis, as a method of depletion when there is excessive secretion; as an astringent vaginal douche in gonorrhea, kolpitis, and particularly when there is ectropion and inflammation of the cervical mucosa. It is here employed in a 1 to 1½% solution. It may also be applied as a powder on a tampon or otherwise. (3) It is applied as a powder in inoperable carcinoma of the cervix; it is the only powder that relieves the pain, controls the hemorrhage, diminishes the discharge, and yet does not cauterize. (4) In hematuria, in a 1 to 16% solution, it controls the hemorrhage and relieves the tenesmus. (5) In hemorrhage from the stomach and intestines and in melæna neonatorum it is given by the mouth in the same doses as the liquor ferri sesquichloridi.

Gottschalk[2] describes stypticin (cotarnin hydrochlorid) as a valuable hemostatic in uterine hemorrhage. It is an amorphous sulphur-yellow powder, giving with water a straw-yellow color that becomes darker on exposure to the light. Internally, it may be given in powder or capsules in ⅚-gr. dose 5 or 6 times daily. Hypodermically, 3 gr. (in a 10% solution) may be injected into the gluteal muscles if the hemorrhage be profuse. Besides its hemostatic properties, it seems also to relieve pain and even to be conducive to sleep. It is contraindicated in threatened abortion.

Dysmenorrhea.—A case of membranous dysmenorrhea is reported by John Madden.[3] The literature of this disease is scanty. Nearly all modern writers, especially those of Europe, regard it as a result of metritis. Schröder remarked that "chronic catarrh is so often found that it may be regarded as the cause of the disease." August Martin, Pozzi, and Lawson Tait express

[1] Centralbl. f. Gynäk., No. 2, 1896. [2] Therap. Monatsh., 1895, H. 12, S. 646.
[3] Jour. Am. Med. Assoc., Mar. 21, 1896.

similar views. The membrane itself is often not an inflammatory product. It has all the histologic characteristics of a normal membrane overgrown. The time occupied in the discharge of the membrane varies considerably, but usually occupies from 2 to 5 days. It may be thrown off slowly and in separate pieces, or it may be passed entire. Duke[1] says that the membrane is obviously composed of the superficial layer of the endometrium, with perhaps an abnormal amount of connective tissue. Duke has met with satisfactory results from the following treatment: The os externum is scarified at intervals of 3 or 4 days between the periods; just before the flow is expected the cervix is dilated, the interior of the uterus is thoroughly curetted, and a spiral wire stem is introduced, which is worn continuously during at least 3 subsequent periods, the patient being directed to take hot vaginal douches even when menstruating. No harm has resulted from the use of the stem, and the patient is able to attend to her ordinary duties. [The use of stem-pessaries of any form and for any condition of the uterus cannot be recommended, on account of the evident risks attendant upon their employment—namely, the danger of uterine perforation and aggravation of the existing inflammation.] Croom[2] objects to the term "intermenstrual dysmenorrhea" which has been applied by the French to the form of dysmenorrhea, so called, which occurs at mid-term, and much prefers the German name of "Mittelschmerz." The condition is a well-marked one, wherein an attack of dysmenorrhea proper is simulated, without, necessarily, any external hemorrhage. It does not at all resemble the premenstrual pain or the continued pain associated with inflamed or diseased ovaries, but it is a condition that occurs definitely each month, at a definite period and for a definite number of days. It may be considered as having three different manifestations: 1. A group of cases in which there are no external manifestations; 2. Those cases in which the pain is associated with an escape of blood; 3. Those cases in which the intermenstrual discharge is associated with a clear discharge. This classification, Croom believes, gives a fair insight into the different states that may lead to the production of this somewhat unusual symptom. (1) With regard to those cases in which no external manifestation accompanies the occurrence of Mittelschmerz, the explanation is probably to be found in the fact that ovulation and menstruation do not in these cases occur simultaneously; that, in addition, owing to thickening of the capsule of the ovary or some such cause, dehiscence of the follicle occurs with pain. (2) In those cases associated with escape of blood there is generally a coexistent endometritis, accompanied by well-marked pain during the passage of clots. Such a condition should scarcely come under the category of Mittelschmerz at all. (3) In those cases in which a leukorrheal discharge occurs with the pain the cause is probably a hydrops Fallopii reaching its full development at mid-term.

The *treatment* of dysmenorrhea will depend upon its cause. In those cases dependent upon cervical stenosis Braithwaite[3] recommends the use of Hegar's

[1] Med. Press and Circ., July 10, 1895. [2] Edinb. Med. Jour., Feb., 1896.
[3] Brit. Med. Jour., June 29, 1895.

dilators under anesthesia on the last day of the menstrual period, immediately after the cessation of the discharge, when the tissues are soft and elastic. The advantages claimed for this method are the avoidance of inflammation and sepsis, of which there is considerable risk when tents are used, and the rapidity with which dilatation can be effected; there is less danger of injuring the tissues, he claims, as they stretch more easily than at other times and the dilatation is more permanent. The danger of the use of morphin in all cases of dysmenorrhea is urged by Macnaughton Jones.[1] Mayet[2] claims excellent results from the use of the following prescription: Iodoform, 5 grams; cocain, 1 gram; oleic acid, 4 grams; sterilized vaselin, 100 grams. A fine aseptic sponge is saturated with the material and applied to the cervix before the patient goes to bed. It is removed in the morning. Care must be taken to prevent cocain-poisoning.

Menopause.—Jouin[3] calls attention to the very intimate relation which, he believes, exists between the menopause and pathologic conditions of the uterus and Basedow's disease. In this relationship he places exophthalmic goiter in the position of an effect or consequence, and not the cause, of the uterine condition. He proves this point by citing 43 cases that came under his own observation in which the uterine lesion was observed to precede the goiter. Moreover, an improvement in the local condition is always followed by the appearance of the general disease. The author believes that this coincidence of these morbid processes is comparatively common, but exophthalmic goiter under these circumstances nearly always presents itself under obscure clinical forms. He suggests, therefore, that this disease should be differentiated and carefully searched for in each case. The menopause may, in like manner, determine the onset of Basedow's disease, and the author is inclined to admit that this form of goiter plays a considerable part in the pathology of approaching age.

Theilhaber[4] from personal observation in several cases infers that in certain individuals who are predisposed to morbus Basedowii it may result from pathologic conditions of the pelvic organs, while, conversely, disturbances of these organs may be directly due to the disease itself. Pregnancy, hemorrhages, and operations, especially castration, may be etiologic factors. Atrophy of the uterus and adnexa may result, as is shown by the fact that menstruation is always scanty or absent in the thyroid disease. That more cases have not been reported is doubtless due to the fact that few patients have been carefully examined with the view of determining this point. This atrophy, he believes, is due to vasomotor influences, and not to anemia, as is usually stated.

As a practical deduction from the foregoing, Theilhaber states that young women with Basedow's disease should be advised not to marry, while the married are warned that the course of the disease may be unfavorably affected by pregnancy and the puerperium, and that the children which they bear are likely to be highly neurotic. Atrophy of the genitals demands no treatment,

A MANUAL

OF

THE MODERN THEORY AND TECHNIQUE

OF

SURGICAL ASEPSIS.

BY

CARL BECK, M.D.,

Visiting Surgeon to St. Mark's Hospital and to the German Poliklinik, New York City, etc.

A Handsome Post-Octavo Volume of over 300 Pages, containing 65 Illustrations in the Text and 12 Plates.

PRICE, $1.25, NET.

"While the leading idea in this Manual has been to write a *practical* book that would in a measure meet the deficiency of the larger works on the subject, yet *theory* could not be entirely omitted, inasmuch as most of the technique of modern wound treatment is founded upon experiments conducted in the laboratory. An important feature of the book is that a stricter line of demarcation than usual is drawn between wounds aseptically performed by surgeons and those otherwise inflicted. In the latter category *antisepsis* asserts its prerogatives, but only as subordinate to *asepsis*."—*Excerpt from Preface.*

"An excellent exposition of the 'very latest' in the treatment of wounds as practised by leading operating surgeons."—*Birmingham Med. Review.*

"A practical and useful description of a carefully considered system of surgical asepsis."—*New York Medical Journal.*

Saunders' New Aid Series of Manuals.

"We can commend this manual to the student as a help to him in his study of venereal diseases."—*Liverpool Med.-Chi. Journal.*

A MANUAL

OF

SYPHILIS

AND THE

VENEREAL DISEASES.

BY

JAMES NEVINS HYDE, M. D.,

PROFESSOR OF SKIN AND VENEREAL DISEASES, RUSH MEDICAL COLLEGE, CHICAGO,

AND

FRANK H. MONTGOMERY, M. D.,

LECTURER ON DERMATOLOGY AND GENITO-URINARY DISEASES, RUSH MEDICAL COLLEGE, CHICAGO.

PROFUSELY ILLUSTRATED.

DOUBLE NUMBER. PRICE, $2.50 NET.

This Manual is intended as a thoroughly practical guide, and represents the latest knowledge of the Venereal Diseases which are included under the heads of Syphilis, and Gonorrhœa and its complications, with very complete instructions for their diagnosis and carefully prepared instructions for their treatment, cure, and alleviation.

The illustrations (some of which are colored) have been selected with the greatest possible care, and with the view of elucidating the text.

Sent post-paid on receipt of price.

W. B. SAUNDERS, Publisher,

925 Walnut Street, Philadelphia, Pa.

"The work may safely be recommended, being modern in spirit and concise and complete."—*The Physician and Surgeon.*

which, in fact, is useless. The prognosis is not hopeless, since their functions may be restored with an improvement in the disease. Local treatment is only required in the rare cases in which the existing anemia is increased by profuse uterine hemorrhages, when curettage is indicated. Neoplasms should, of course, be dealt with according to the usual rules. H. L. E. Johnson[1] reports 3 cases of atresia of the uterus occurring after the menopause. He believes that this occurs pathologically much more frequently than is supposed. The atresia is physiologic only after complete atrophy of the body of the uterus and its endometrium. The symptoms of the condition mislead by directing attention to the nervous system more particularly than to the true seat of disease. The uterus during the menopause, and until completely atrophied, should be kept under careful observation, all inflammatory, catarrhal, and other abnormal conditions cured, and the canal kept pervious by the frequent passage of the uterine sound. Atresia of the cervix, without complete atrophy of the uterus, should be operated upon at once, even in advance of symptoms.

[Castration for the cure of Basedow's disease has been advocated by Blocq, but there are no scientific grounds for its support.]

Tachycardia in women may, according to Baldwin,[2] occur at any period of life. It is rare, however, before puberty and after 50 years of age, and is most often seen during the menopause. Those who pass through the change early are more liable to it than those who menstruate until later in life. It occurs with special frequency when the menopause has been prematurely induced by surgical operation or by disease. Kisch, who has seen 28 cases in 5 years, concludes that it is due to the hyperplasia of the stroma of the sexual organs. This increase of connective tissue acts in some way upon the terminal fibers of the sympathetic nerves. As regards treatment, Baldwin remarks that if tachycardia be due to excitation, opium would give the best results, while, on the other hand, if it result from paralysis of the pneumogastric, digitalis would be an ideal remedy. These two agents are the best remedies at our command, but in many cases they prove utterly worthless. Galvanism has been most effective in Baldwin's hands, but its action was limited to the time in which the current was applied.

UTERINE ANOMALIES.

Congenital defects of the reproductive organs of the woman are, according to Dorland,[3] not so rare as one would at first sight imagine. In about 3500 women personally examined by him in the past 10 years, in 3 instances there were detected double uteri; once there was found a double vagina in association with a duplex uterus; in 1 instance there was a rudimentary condition of the uterus and vagina, the latter measuring in depth not more than 2 in., while the uterus, examined per rectum, was not larger than a hazelnut; and in 1 case there was apparently an entire absence of the uterus, while the rudimentary vagina measured 1½ in., the organ ending abruptly above in a culdesac.

[1] Jour. Am. Med. Assoc., Dec. 7, 1895. [2] Brooklyn Med. Jour., Nov., 1895.
[3] Phila. Polyclinic, Nov. 30, 1895.

The variety of the congenital defect of these organs depends upon the time in embryonic development at which the disturbing factor begins to act. Most commonly this occurs late in embryonic life, after the ducts of Müller have attained their full maturity, but prior to the time at which they have fully coalesced to form the generative organs. The various forms of double uteri and vaginæ are thus evolved. If, however, the arrest of development occur prior to the formation of the uterus by fusion of these ducts or prior to the development of the ducts of Müller themselves, either one or both of these structures fail to appear; in the former instance there results a uterus unicornis, or one formed by but a single Müllerian duct; in the latter case no trace of the uterus can be detected on manipulation, even when the patient is completely relaxed under the influence of an anesthetic. If, however, the pelvic cavities of such individuals could be examined carefully after death, it is not improbable that in almost all, if not in every case, some trace of the missing structures could be detected, microscopically if not macroscopically, in the form of fragments of rudimentary muscular tissue. To all intents, however, the uterus is absent in these women, and such cases must be handed down in medical records as instances of congenital absence of that organ.

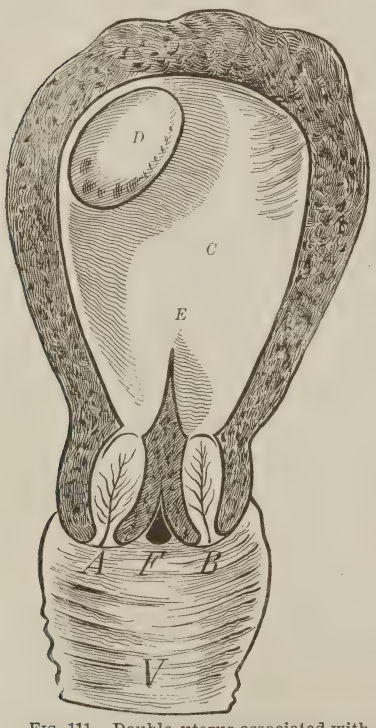

FIG. 111.—Double uterus associated with submucous fibroid tumor: *A*, Right cervix; *B*, left cervix; *C*, common cavity for the body of the uterus; *D*, submucous fibroid; *E*, remains of septum just above the internal os on each side; *F*, falciform fold of vaginal mucous membrane; *V*, vagina (Lancet, Mar. 21, 1896).

Lewers[1] reports a case of double uterus associated with a submucous fibroid tumor (Fig. 111) in a woman, 38 years of age, who had been married 14 years, but had never been pregnant. The catamenia appeared when she was 15 years old, but she was not regular until she was 21, several months intervening at times between the periods. For 7 months before examination she had suffered from increasing metrorrhagia and dysmenorrhea. Examination under anesthesia revealed a curious falciform fold of mucosa (*F*) at the upper part of the vagina, running from before backward and from right to left; this separated the two vaginal portions of the cervix uteri. A sound introduced into each cervix passed $4\frac{1}{2}$ in. The submucous fibroid, the size of a large walnut, was felt attached at the fundus of the enlarged uterus and to the right side. It was pedunculated, and readily removed by torsion. Further examination showed that there was but one uterine cavity, which connected with the two cervical canals. There

[1] Lancet, Mar. 21, 1896.

was a sort of spur (*E*) felt a little above the level of the internal os. [The case is of especial interest on account of the unusual association of the fibroid neoplasm with the rare congenital defect; also on account of the unusual situation of the septum between the two uteri. More generally it is the upper part of the septum that persists, while that corresponding to the cervical region disappears.]

A case of absence of the uterus and its adnexa, together with a rudimentary condition of the vagina, is reported by Mehrer;[1] a case of double uterus and double vagina is reported by Sprigg;[2] Jacobi[3] reports a case of absent uterus; while Shoemaker[4] reports 1 case of uterus cordiformis, 1 case of partial vaginal septum, and 2 cases of infantile uterus. Clapham[5] records a case of congenital absence of the uterus in a young girl, 19 years of age, who had never menstruated. An examination of the abdomen revealed two lumps at the upper end of the inguinal canals about the size and shape of ovaries, which organs they probably were. The patient had suffered from anemia for 2 years. At 16 years of age her breasts began to develop, and became very full and large. Pubic hair only appeared 3 months before examination and was very scanty in amount. The girl had suffered at intervals from seizures somewhat resembling attacks of minor epilepsy. Under chloroform examination the external genitals were found to be typically feminine in character, though presenting a somewhat youthful appearance, the vulvar slit coming very far forward. The labia were well developed, the clitoris and meatus urinarius normal in size and position. The vagina was 2 in. in length, admitting the index finger with difficulty, and was found closed at the upper end. The uterus was totally wanting. The patient had never had any sexual feelings. Jacobi, who has made a close study of these abnormal conditions, concludes that there may be—1. Absence of the uterus with rudimentary development of the external genital organs (atrophy of the middle segment of the genital apparatus, imperfect development of the external segment); 2. Absence of the uterus with hernia of the ovaries; 3. External organs ambiguous and rudimentary, internal organs masculine; 4. External organs ambiguous, habitus masculine, nature of deep gland uncertain; 5. External organs masculine, internal feminine, habitus feminine; 6. External organs feminine, internal masculine; 7. Middle segment of the generative organs bisexual, external masculine; 8. Bisexualism of the three segments.

UTERINE INFLAMMATION.

Metritis.—Sellman[6] strongly endorses the old classification of Thomas of disease of the uterine substance into "chronic metritis" and "areolar hyperplasia." He claims that there is a marked difference between the two. There is a chronic inflammatory condition in which the uterus is soft, edematous, increased in size, and containing an increased amount of blood. This is

[1] Wien. med. Woch., Sept. 28, 1895.
[2] Am. Jour. Obst., July, 1895.

[5] Quart. Med. Jour., Sheffield, Apr., 1896.
[6] Am. Jour. Obst., Nov., 1895.

true metritis. When there is permanent blood-stasis the vessels become distended, their walls lose their tonicity, and certain elements of the blood contained within them, by a method of exosmosis, pass into the cellular tissue or perhaps even between the muscular striæ. The size of the organ is increased by this excessive amount of blood and serum. There is pressure made upon sensitive nerve-filaments which gives rise to the pain and sensitive condition experienced by patients suffering from this disease. Plastic material is thrown out into the walls of the uterus. Nature attempts to take care of this material, and does absorb it to a certain extent, but her powers are insufficient in many instances to take up from the uterine tissues the material thus thrown out of the circulation; there results, therefore, an overnutrition of the muscular fibers and of the utricular glands, with consequent thickening of the walls of the uterus and increased secretion. This accounts for two conditions present in uterine hyperplasia—namely, increase in size and weight, and the enormous quantity of glairy, white-of-egg secretion. Bertelsmann[1] finds as the result of his microscopic studies that in cases of metritis, carcinoma, and interstitial fibromyoma of the uterus the muscle undergoes a hyperplasia, the tissue becoming softened and stratified and the cells swollen, much as in the pregnant uterus. Duncan[2] also emphasizes the hypertrophy of the connective tissue, that is also usually associated with some muscular hypertrophy. The arteries and veins are much thickened by hypertrophy of the tunica adventitia. The connective tissue remains permanently hypertrophied, and does not undergo cicatricial contraction.

At the French Congress of Internal Medicine, held at Bordeaux, du Magny[3] described a special form of metritis developing in the course of uremia, and characterized by a vaginal discharge of varying degree and color, of irritating properties, and manifesting an odor like that present in cases of uterine carcinoma. On palpation the uterus in this disease feels enlarged and softened in places. On ocular examination the cervix appears reddened and swollen, and its lips are the seat of numerous small prominences of varying size, resembling nodules of epithelioma. All of these phenomena disappear with the other uremic manifestations.

Madlener[4] states that Neisser's gonococcus is capable of penetrating the muscular tissue from the endometrium, and there causing inflammation which may proceed to the formation of abscesses. This occurs most frequently in puerperal cases. The gonococcus soon disappears from the muscular tissue either by destruction or by emigration. By invasion of the serous membrane from the endometrium the peritoneum may be infected without any tubal disease. In this way perimetritis in gonorrhea may be explained. In sections from a uterus removed 7 weeks after confinement Madlener demonstrated the presence of gonococci among the muscular fibers. Forms clearly showing diplococci and corresponding in size to the gonococci were found in sections taken longitudinally from the fundus. The cocci were found in pairs,

[1] Arch. f. Gynäk., 1895, B. v. H. 1.
[2] Lancet, July 20, 1895.
[3] Mercredi méd., 1895, No. 41, p. 487.
[4] Centralbl. f. Gynäk., Dec. 14, 1895.

usually between the cells of inflammatory exudate, and sometimes between the muscle-cells. They were found in sections taken from the anterior and posterior walls of the body and from the cervix. The gonococci remain for years in mucosæ, and can be demonstrated there, but the uterine muscular tissue is not a favorable soil for a prolonged stay or for propagation. Madlener believes that many uterine abscesses are caused by the gonococci.

For the relief of chronic parenchymatous metritis Talley [1] employs irrigation of the uterus with 1 or 2 gallons of alkaline solution at a temperature of 110° F., using for this purpose a specially devised irrigating tube providing a return flow, and small enough in diameter to pass through a No. 15 French catheter gauge. The action of the application of heat and moisture is to cause, first, vasomotor dilatation, and subsequently vasomotor contraction. The mucous secretions are dissolved and washed away by the alkaline solution, leaving a clean membrane. Following the irrigation, about 20 minims of a mixture of equal parts of Churchill's iodin and carbolic acid are injected into the uterine cavity by means of a Braun syringe, and a cotton tampon, well saturated with glycerin, is tucked neatly against the cervix. This is to support the uterus and to deplete it by the affinity of glycerin for the serum of the blood. Such treatment is applied twice or thrice a week. Conjoined with the local treatment care is given to securing mild exercise, nourishing diet, and the administration of iron, arsenic, and strychnin.

[This method is only applicable to cases in which the *cervical canal is patulous;* unless such cases are selected the physician will be embarrassed by severe uterine colic following his treatment.]

Endometritis.—An elaborate classification of endometritis based exclusively upon the result of bacteriologic research is offered by Winckel [2] to replace the old groupings according to the anatomic characteristics, the symptoms, or the etiology. According to the new system, endometritis may be divided into two general classes: 1. Simple endometritis, or that in which bacteria have not been discovered. This class includes—(*a*) Endometritis due to troubles of the circulation; (*b*) Endometritis from intoxication or infection; (*c*) Endometritis post abortum or decidual; (*d*) Endometritis exfoliativa. 2. Purulent endometritis, or endometritis of bacterial origin, comprising—(*e*) Gonorrheal endometritis; (*f*) Tuberculous endometritis; (*g*) Septic endometritis; (*h*) Saprophytic endometritis; (*i*) Diphtheric endometritis; (*j*) Syphilitic endometritis; (*k*) Blastomycetic endometritis; (*l*) Protozoic endometritis, or endometritis from protozoa.

While this classification corresponds to our present knowledge of the subject, it is probable that we shall find bacteria in some of the inflammations now classified as simple. *Simple* endometritis occurs at all ages. It is due to disturbances of circulation caused most frequently by tight corsets, also by constipation and the introduction of foreign bodies in the vulva or vagina. At a more advanced age it is usually due to some one of the numerous lesions incident to labor, neoplasms, or to some affection of the ovaries, as pointed

[1] Physician and Surgeon, Dec., 1895.

[2] La Sem. méd., 1895, No. 30.

out by Brennecke and Czempin. Lesion of some remote organ can bring about a congestion of the uterus and become the secondary cause of an endometritis. In the group resulting from *intoxication* are included those following extensive burns, those caused by phosphorus-poisoning, and those following infectious diseases, as cholera, small-pox, or scarlet fever. *Endometritis postabortum* is due to retention of more or less of the membranes after a miscarriage or abortion, and the irritation and congestion due to their presence. In *endometritis exfoliativa* there is no purulent infiltration; the false membrane is expelled at more or less regular intervals, but without suppuration. In the intervals there are usually no leukorrhea and discharge from the uterus.

The endometritides of bacterial origin are arranged in the following order, according to their frequence: Gonorrheal, septic, saprophytic, and the less common forms, tuberculous, syphilitic, diphtheric, blastomycetic, and protozoic.

As a common cause of endometritis among young women should be mentioned imprudence during menstruation, cold baths, foot-baths, sitz-baths, and masturbation. Certain diseases, as chlorosis, anemia, Bright's disease, morphinomania, and hysteria, can also cause the disease. As age advances the sexual functions with their complications are the important factors in producing the disease.

As regards frequency, endometritis is probably more often met with than any other disease affecting the female genitals. Among 21,685 women treated at the clinics of the Prussian universities, 2236, or over 10%, were suffering from endometritis. The symptoms should be divided into three groups, as follows: local symptoms, symptoms of neighboring organs, and general symptoms. The first class includes anomalies of secretion, menstruation, and conception. The secretion is variable, sometimes abundant, especially in senile endometritis, sometimes inconsiderable. It is also variable in color. Often it is difficult to determine whether it come from the cervix or the body of the uterus, although catarrh of the body is much less frequent than from the cervix. The same can be said of hemorrhage; it is sometimes abundant, sometimes slight, and sometimes fails entirely. The pain depends upon diverse causes. It is expulsive when there is an obstruction of any kind or a membrane to be expelled. It is "dull" or "shooting" when the nerve-endings are denuded by erosions or ulcerations at the cervix.

The results of endometritis are—swelling of the mucous membrane, destruction of the ciliated epithelium, sterility, and abortion if the patient become pregnant.

Only a portion of the cases begin with an acute stage; the others are chronic from the start. This is especially true of those cases of endometritis met with in chlorotic and anemic individuals. An explanation of the persistence and severity of this form of catarrh can be found in the complex structure of the tissue and the numerous and complex functions which it performs.

Bumm[1] believes that the bacteria sometimes found in the uterus are there

[1] La Sem. méd., 1895, No. 30.

by chance and have no pathologic significance. He does not believe that chronic endometritis is always due to an acute or subacute invasion from streptococci or gonococci. Döderlein[1] of Leipsic, speaking on the subject of the relation of endometritis to the process of generation, adopted the three heads: (1) The influence of endometritis on pregnancy, parturition, and the sequelæ of labor; (2) The sexual act as a cause of endometritis; (3) Infective endometritis after childbirth. Fungoid endometritis, continuing during pregnancy under the form of a decidual endometritis, is a frequent cause of abortion, quite as potent as syphilis, but differs from that disease in that after vigorous treatment the mother may produce a perfectly healthy child notwithstanding numerous previous abortions. Interstitial endometritis, either acute or chronic, is the chief cause in the production of decidual endometritis, and in rare cases we see forms of glandular endometritis running into cystic degeneration (hydrorrhœa gravidarum). Most of the adherent placentas are also due to interstitial endometritis.

In describing the pathology of endometritis Duncan[2] adopts the old classification of chronic hemorrhagic or villous endometritis, chronic catarrhal or glandular, and chronic interstitial endometritis. In the villous form the mucosa is greatly hypertrophied, perhaps to 4 or 5 times its usual thickness; it is deeper in color, and, instead of being smooth, has become fungoid and the projections may form true polypi. In some cases there are found small transparent vesicles, which under the microscope are seen to be dilated glands, the openings of which are closed by connective tissue. The interglandular tissue is very vascular. In the glandular or catarrhal form the glands are enormously increased in size and become convoluted at their deep extremities; there is also an increase in their number, so that both hypertrophy and hyperplasia coexist, but otherwise the glandular tissue is normal in structure. In the interstitial form a new connective tissue is developed between the glands, and in some parts it converts the latter into cysts; in others, of longer duration, the glands may have disappeared altogether, so that the mucosa is represented by a layer of connective tissue lined by epithelium.

Müller[3] has noted the condition of the pelvic organs in 157 cases of influenza, 21 women being pregnant. Of the latter 17 aborted. Of the nongravid women, all but 3 showed symptoms of uterine disturbance, either hemorrhage or an aggravation of the previous troubles. Hemorrhagic endometritis commonly developed, as in cholera, typhus, and other infectious diseases. After the decline of the disease the uterus was frequently found to be enlarged and evidences of chronic endometritis were present, which seemed to be directly due to the influenza.

Two cases of **tuberculous disease** of the uterus are described—1 by Emanuel[4] of primary tuberculosis of the cervix, and 1 by Reverdin and Buscarlet[5] of secondary tuberculosis of the uterus involving the external os

[1] La Sem. méd., 1895, No. 30.
[2] Lancet, July 20, 1895.
[3] Münch. med. Woch., 1895, No. 41.
[4] Zeit. f. Geburtsh. u. Gynäk., Bd. xxix., 1895.
[5] Rev. méd. de la Suisse Rom., Aug. 20, 1895.

in a woman 30 years of age. In the latter case a soft circular ulcer was found on the cervix, its base rose-colored and covered with very fine yellow points. Curetment of the cavity and of the surface of the ulcer removed a red pulp mixed with small yellow masses, which contained, on bacteriologic examination, numerous tubercle bacilli. In Emanuel's case the primary lesion was found in the cervix uteri, the vagina, uterine cavity, and perineum being secondarily infected. Only 2 cases similar to this have been reported. The perineum was found covered by a sloughing ulcer 4 in. in length and $\frac{3}{4}$ in. in breadth. A tumor the size of an apple was attached to the cervix, causing secondary ulceration of the surrounding vagina. The uterus was enlarged and anteflexed. There were no physical signs of pulmonary involvement.

T. S. Cullen[1] states that tuberculosis of the endometrium is usually secondary to that of the tubes, and so is confined at first to the fundus of the uterus. It may extend upward from the vagina, being due to infection through coitus. The disease may be divided into (1) miliary and (2) chronic diffuse, the latter form being by far the more common. In the early stages tuberculous endometritis cannot be recognized by the naked eye. Yellowish-white nodules appear beneath the surface, increase in size, making the mucosa rough, and then form ulcers that are shallow and appear wormeaten or with undermined edges. The entire endometrium becomes caseous, and an accumulation of this material may, if the cervix be occluded, simulate pyometra. The process extends to the uterine muscle, and may cause rupture of the uterus. The tubes, being first affected, usually show caseation macroscopically by the time the process has reached the uterus. The ovaries are usually normal. There are no fixed symptoms of the disease; those present are due to the disease of the tubes. Menstruation may be irregular. *The diagnosis can be made by microscopic examinations of scrapings*, except in the early stages, when the process is confined to the cornua and is not reached by the curet. The scrapings may appear normal to the naked eye, even when the disease is advanced. The treatment consists in the following: Curetting of the uterus has been advocated, but usually this leaves some of the mucosa intact, especially at the fundus, where the process is most advanced. As tuberculosis of the endometrium is usually associated with that of the tubes, it is best to remove both uterus and tubes if the latter are found to be tuberculous when the abdomen is opened for exploration or operation.

Colpe[2] reports a case of obstinate cervical endometritis that resisted the usual astringents and caustics. Finally, mycotic spores were found in the secretion, when lactic and salicylic acids were used locally on account of their known antibacterial effect, with prompt relief. The writer states that *mycosis of the cervical canal* is probably a more frequent cause of obstinate catarrh than is generally supposed.

In the discussion on endometritis before the German Gynecological Society, Wertheim[3] made the following deductions with regard to *gonorrhea of the*

[1] Johns Hopkins Hosp. Rep., vol. iv. Nos. 7, 8. [2] Centralbl. f. Gynäk., 1895, No. 27.
[3] Ibid., 1895, No. 26.

uterus: Next to the urethra the uterus is the favorite seat of gonorrheal infection. As a rule, the uterus is directly infected, and the disease is not infrequently confined to that organ. In uterine gonorrhea there is nearly always present an acute interstitial endometritis, though in a few cases the process partakes of the nature of the more chronic glandular variety. In many instances there is an inflammatory infiltration of the muscle, with hyperplasia of the vessel-walls.

Sexton[1] prefers the term **postclimacteric endometritis** for that variety of endometritis occurring in women after the menopause. He thinks that the disease is different from the so-called *atrophic endometritis* that has been described. The most striking symptom is the discharge, which is watery, semipurulent, free from blood, barely staining the linen, and irritates the vagina and vulva as well as the surrounding skin. A characteristic odor is present, sometimes even more offensive than that of carcinoma. Abdominal pain and pain in the back are usual accompaniments, as well as progressive emaciation and invalidism; furthermore, a slow form of sepsis seems to invade the constitution, and the skin assumes a sallow appearance. In all of the cases there seems to have been an antecedent history of uterine disease. They are of long duration, even covering a period of 10 or 12 years. One case is reported by Sexton, and 3 by Maurange. Bell[2] considers endometritis as the one great cause of sterility, and also of flexions and oophoritis.

In the line of *treatment* Fenwick[3] believes that local bloodletting is, in certain cases, a most important and powerful remedy. The local abstraction of blood may be attained by using leeches or by scarification. The leeches are used externally only. He regards them as objectionable for use on the cervix, not only because they draw very little blood and leave a wound that heals badly in some persons, but because there is danger of their entering the uterus, and they may even pass through the Fallopian tube into the abdominal cavity. When the cervix uteri is deeply congested, deep-red, bluish, or purple in color, local depletion by scarification generally gives immediate relief. In cases of subacute ovaritis or obscure throbbing pain in the pelvis cupping or leeching externally frequently relieves the patient immediately.

Irrigation of the uterine cavity is one of the most generally employed methods of treatment for endometritis. Recently, Roesing[4] has conducted a series of novel experiments with a view to determining the extent to which the uterine cavity is reached by injections. For this purpose he employed freshly extirpated uteri, injecting colored fluids through different varieties of catheters, so that the endometrium would retain the staining. He found that the freer the outflow the less thorough was the irrigation of the cavity. The larger the amount of fluid which was injected, the more deeply did it penetrate below the surface. Sections of the uteri showed that healthy tissue was more deeply stained than diseased. He concludes that medicaments are brought most thoroughly in contact with the endometrium when introduced on applicators

[1] Am. Jour. Obst., Nov., 1895.

[4] Arch. f. Gynäk., 1895, Bd. xlix. H. 2.

or by means of a Braun's syringe. [This probably would be true were it not for the sphincteric action of the cervical muscle, whereby fluids on the applicators are squeezed out before they enter the uterine cavity. The intrauterine pipet is therefore the better mode of treating the uterine mucosa.]

[The *curet* as an agent in intrauterine treatment has been very thoroughly investigated during the year, and, as might be expected, still holds its place as a most valuable instrument in the properly selected class of cases. Dumontpallier's claim that curettage as an operation is losing ground in France cannot be substantiated. Only when employed in cases not appropriate for such a procedure will unsatisfactory results be obtained.] Martin[1] enumerates the following indications for the use of the curet: (1) In endometritis, after failure of complete rest, hot douching, and tampons, with occasional swabbing with iodin, and in the absence of evidence of associated pelvic mischief. (2) In incomplete emptying of a pregnant uterus. If there be evidence of retained septic products, it is useless to dally with douches; curet as soon as possible prior to the onset of septicemia or pyosalpinx and general peritonitis. (3) In carcinoma as a palliative. In myoma it is useless, and other operative procedures should be adopted. (4) As a diagnostic agent.

Dorsett[2] regards the blunt curet as a dangerous instrument. The instrument with a sharp-cutting edge, properly constructed, is a most useful one. In order to secure a good scraping instrument the sharp edge should stand at an angle of 60° to the shaft or handle. A greater angle will not scrape thoroughly, and a lesser angle is liable to incise the uterine wall unless used with much care. According to Bouilly,[3] the curet can only be used with benefit in morbid conditions of the uterine mucosa and its subjacent tissue. In those cases attended with more profound alterations of the parenchyma and glands, with sclerous or sclerocystic degeneration (total parenchymatous metritis, cervical hyperplastic glandular metritis), no good can be expected from its use. In all cases of superficial infection, in the hemorrhagic forms of endometritis, in the caseous or caseiform metritis of aged women, and in the early stage of catarrhal metritis, it is of benefit. Pryor[4] regards the endometrium not as a mucosa, but as a lymphoid organ possessing no glands. The uterine follicles dip down into this tissue and are everywhere surrounded by lymphoid cells. This conviction has been forced upon him by the lack of physiologic function in the endometrium of the very fat; the remarkable activity in the absorptives that follows the removal of the uterus, similar to that noted after destruction of Peyer's patches by typhoid fever; the action of thyroid extract upon the absorptives, directly the reverse of that brought about by the removal of the mass of lymphoid uterus; the effect of hysterectomy upon the progress of phthisis pulmonalis; and the synchronous development of the thyroid and lymphoid endometrium. [There is nothing in the literature of the anatomy of the endometrium that upholds this theory of Pryor's; on the other hand, there is much to disprove it. Pryor himself in advancing the theory offers no

[4] Am. Gyn. and Obst. Jour., Jan., 1896.

convincing proofs as to the truth of his assertions. For the present, therefore, the subject must be considered as not proven.]

The possible accidents of curettage are well grouped by Pichevin[1] as follows: 1. Abortion due to the rough use of the instrument within the gravid uterus, of which many cases are on record. 2. Septic infection, which has not infrequently resulted fatally in preaseptic days. 3. Rupture of a pyosalpinx, as in a fatal case reported by Rochet. In the event of such an accident vaginal hysterectomy or abdominal section should be performed without delay. 4. Atresia of the uterus after curettage has been noted by Polaillon and Fritsch, but is rare. 5. Perforation is the most frequent accident, a case being reported as early as 1854 by Richard, who, as well as Nélaton, called attention to the fact that it is often unattended by serious results. The same observation has been made by many subsequent writers. As regards the causes of perforation, Pichevin finds that softening of the uterine wall following pregnancy is the most common, perforation of the nonpuerperal uterus during curettage being quite rare. Frequent childbearing, tuberculosis, and possibly cardiac disease, seem to cause certain degenerative changes in the muscular tissue. If the softened uterus be retroflexed and fixed by adhesions, there is especial liability to the accident. The seat of the puncture varies, being most apt to occur at the angle of flexion when the uterus is retroflexed and adherent. The most common point is at the cornua, in the neighborhood of the tubal orifices, where the wall is thinned: as Lefour has shown, inflammatory lesions are most marked in this region. If a perforation is caused, Pichevin believes that in the majority of cases it will be sufficient to tampon the uterine cavity simply with gauze. Prolapsed omentum should be replaced if possible, or, this failing, the prolapsed portion may be excised.

A very rare accident after curettage is obliteration of the uterine cavity. If the operation be done in a too vigorous manner during the stage of fatty degeneration of the uterus following the puerperium, the muscular tissue may be so torn up as to induce complete union of the uterine walls. Outside of the puerperium such an accident could scarcely happen. Cases have been reported by Fritsch, Küstner, and Veit.[2] Veit believes that when the uterine cavity is completely obliterated it is useless to reopen it.

[We have known of several cases in which, after curettage for chronic metritis, there was an obstruction of the cervical canal for several months. One case returned home to the country, missed her first period, but had considerable pain; the second period was marked by severe, almost unbearable, pains, but no flow; the third period the pain became so great that we were telegraphed to hold ourselves in readiness to come and operate. The next day the telegram was followed by a letter saying that suddenly the patient had bled an enormous quantity, the hemorrhage stopped suddenly, the pains disappeared, and the patient was well. The uterine contraction had clearly overcome the obstruction. The second case followed much the same course.]

UTERINE DISPLACEMENTS.

Normal Position of the Uterus.—Penrose[1] remarks that no uterine ligament is inserted higher than its origin in the uterus; therefore these ligaments do not suspend the uterus when this organ is in its normal position. The main factor tending to hold the uterus in its normal position in the pelvis is the retentive power of the abdomen or the equality of pressure in all directions.

Mackenrodt[2] summarizes a paper on this subject as follows: Contrary to the usual statement, the pelvic fascia is not perforated by the vaginal canal, but surrounds and sends off to the cervix and vagina firm bands, those attached to the latter forming with it the strongest point of resistance to the abdominal pressure. The cervix uteri is so attached by the pelvic fascia as to occupy the position of slight anteflexion seen in the embryo. This normal flexion takes place in the cervix, the corpus uteri being inclined forward, while its axis remains perfectly straight. The uterus is kept in a position of anteversion by its ligaments, but remains passive in the direction of the upper portion of the cervix. Its own weight and the intraabdominal pressure also assist the organ in maintaining its normal position. The perineum offers only a slight resistance to the intraabdominal pressure. The real support of the uterus in its normal position is afforded by the attachment of the pelvic fascia to the cervix. Hence the deduction that the true cause of posterior displacements of the organ is to be sought for in relaxation of this fascia. In prolapsus the same condition is present plus atrophy of the muscles forming the pelvic floor, which may be due as much to general as to local causes. [It must be remembered that the normal position of the uterus is a variable factor dependent upon a number of associated causes, preeminent among which is the retentive power of the abdomen, which is itself founded upon an integrity of the pelvic floor and abdominal wall. The physiologic retroversion of the uterus due to natural accumulation of urine in the bladder is just as truly a normal position of the uterus as is the moderate anteflexion when the bladder is evacuated, and this great mobility of the uterus is one of the strongest proofs of its absolutely normal condition, everything else being equal.]

Lateral Displacements of the Uterus.—E. J. Ill[3] read a paper on this subject before the American Association of Obstetricians and Gynecologists at Chicago in September. He enlarges upon the importance of this abnormal condition, and thinks it has been generally overlooked, the patient's symptoms being attributed to other ailments. He has collected from his case-book all cases of lateral displacement except such as had presented tumors. In 14.2% of his patients there had been lateral displacement. He especially mentions those cases which he considers congenital, and in which the pain was referred to the elongated broad ligament. In these patients the symptoms begin early in the patient's sexual life, in the severer cases pro-

[3] Am. Jour. Obst., Nov., 1895.

gressing gradually to complete invalidism. The nonoperative treatment consists in endeavoring to elongate the shortened ligament by the use of dry wool or oakum tampons pushed between the cervix and the ilium on the side of the shortened ligament, keeping the tampon in place by a second and third one. All this is to be retained for 48 hours. A hot douche, with the patient on her knees and elbows, twice daily, when the tampons are *in situ*, is also ordered. He relates 2 cases of extreme suffering in which total extirpation of the uterus, tubes, ovaries, and broad ligament had been deemed advisable after years of unsuccessful treatment, in both of which the patients had been much relieved of their suffering by this method.

Uterine Prolapse.—Edge[1] states that uterine prolapse is due to—1. Deficient support from rupture of the perineum, with loss of a fixed point for the perineal muscles, and stretching of the levator ani muscle; 2. Deficient tone of the pelvic floor, including the bladder, urethra, and vaginal walls; 3. Intraabdominal pressure. To restore the uterus to its normal position it is necessary to repair the perineum, restrain abdominal pressure, remove congestion, and induce adhesion between the anterior rectal and posterior vaginal walls.

Niebergall[2] gives the results of the surgical treatment of prolapsus at the Bâsle Clinic in 110 cases. The operations usually performed were amputation of the cervix and anterior kolporrhaphy according to Fehling's method, followed 2 weeks later by Hegar's kolpoperineorrhaphy. Fehling denudes two long ovals on either side of the median line of the anterior vaginal wall, and unites their edges with silver wire. Seventy patients were seen or heard from, and of these 57 were cured at periods varying from 1 to 6 years after operation, 7 of the women having since borne children. The ultimate results were 20% better than those obtained by the ordinary operation in the anterior wall.

Gaertig[3] reports unfavorably upon the treatment of uterine prolapse by Freund's method. In 7 cases operated upon by him only 2 remained cured at the expiration of a year. Condamin[4] reports a case of ventral fixation for prolapse of the uterus. Rendu does not regard this as a good operation, and believes that 18 months is too soon to judge of its ultimate results. Graefe[5] reports a case of total prolapsus in which he was compelled to perform an extirpation owing to his inability to replace the uterus within the pelvis. In 4 weeks' time there followed a considerable prolapse of the anterior vaginal wall, and Fehling believes that in these cases the total extirpation should be supplemented by an anterior and posterior kolporrhaphy.

Baldy[6] describes a new operation for uterine prolapse (Plate 3). The procedure is in all essentials an abdominal hysterectomy by amputation at or below the internal os. The points to be observed are—to include both the ovarian arteries and the round ligament in the first ligature on each side of the uterus; to place this ligature as near the pelvic wall as possible, so as to leave but a

[6] Am. Jour. Obst., vol. xxxiii. No. 4, 1896.

small amount of broad ligament behind with the stump; to place but one other ligature on each side of the uterus, this ligature to include the uterine artery with as little other tissue as possible: this leaves both broad ligaments open; to amputate the uterus as low on the cervix as possible. Plate 3, Fig. 1, shows this part of the operation completed, together with the second step—namely, the placing of the sutures. A glance at this illustration shows the suture *in situ*, while inspection of Plate 3, Fig. 2, shows the suture tied with the parts drawn into place. The suture should be composed of heavy ligature silk, and in the course of its application it includes both the ovarian and uterine stumps, *deeply* placed well *back* of the ligatures. It will further be noted that the sutures include the sides of the cervical stump. It can readily be seen that the effect of tying these sutures is to lift up the stump of the cervix together with the vagina, and to bring it in close approximation with the ovarian stumps, doubling the opened broad ligaments together (see Plate 3, Fig. 2). Adhesions take place throughout the full extent of the doubled broad ligament, and most surprisingly firm support is given from above to the vagina. Plate 3, Fig. 3, shows the peritoneum drawn together by a catgut suture over that portion of the cervical stump that remains uncovered after the two sutures are tied. The results accomplished by this operation are as follows: The weight of the heavy uterus is removed; the overstretched vagina is lifted high up and held firmly in place; the supports utilized are the natural supports of the uterus and upper portion of the vagina—the broad ligaments; the cervix remains a pelvic organ, as is natural to it. The immediate and remote result, as regards fixation of the upper part of the vagina, is perfect. The plastic operations on the vagina Baldy judges to be absolutely essential as an adjunct to this as well as to any other similar procedure. He has performed this operation in 8 cases with the most satisfactory results.

Retrodisplacement of the Uterus.—By retroposition—or retrocession, as he prefers to call it—Jarman[1] means that the uterus has receded toward the sacrum without any turning around on its transverse axis. He has observed 62 cases with this displacement. Retrocession of the uterus is due to chronic inflammation and consequent shortening of the uterosacral ligaments; and as a result of this the organ is drawn backward and upward, so that it lies nearer the brim of the pelvis than before, and the ligaments can easily be felt as tender, firm bands running from the cervix toward the sacrum. Uterine mobility is lessened and tension on the cervix causes pain. Pain in the sacral and lumbar regions is the most constant symptom, and this pain is increased on standing or by constriction of the waist with tight clothing. Any attempt to move the uterus will cause pain, which is referred to the back; the normal motility of the uterus is distinctly impaired. Nonoperative treatment must be prolonged if it is going to give satisfactory results. If any morbid condition of the cervix exists, it should be treated, and an effort made to lift up the uterus and so lessen the strain on the uterosacral ligaments. This may be done by means of a tampon or pessary. Jarman has not seen any good

[1] Am. Jour. Med. Sci., Nov., 1895.

PLATE 3.

Baldy's operation for prolapsus uteri (from drawings prepared specially for this work).

results from hot douches in these cases. From time to time an attempt should be made to stretch these ligaments by traction made on the cervix with a volsella, the examining finger being placed meanwhile in the posterior vaginal fornix. The internal administration of red iodid of mercury appears to assist in the cure. If local treatment does not succeed, the uterosacral ligaments should be divided. This can be done easily and safely by making a transverse incision through the posterior fornix so as to lay open the pouch of Douglas. If traction be now made upon the cervix, the ligaments are rendered tense, and can be divided without difficulty by means of a pair of blunt-pointed scissors. The incision is then closed by sutures. Jarman's conclusions are: 1. Retrocession has been often overlooked as a cause of pelvic pain; 2. The condition of the uterosacral ligaments must be considered in the treatment of anteflexion; 3. Retrocession can be easily relieved by operative measures if local treatment does not succeed.

[**The operative treatment of retroflexion** still excites much controversy. Suspensio uteri as yet remains the safer and preferable method, although itself attended at times by some objectionable sequelæ. Vaginofixation, while enthusiastically advocated by a limited number of operators, must ever be objectionable for the same reasons that vaginal incision in uterine fibroids or pyosalpinx is—namely, the inability to secure absolute asepsis and the danger of injury to adjacent structures, not to mention the disastrous consequences of this operation upon subsequent pregnancies and labors. Alexander's operation still survives in its oft-modified forms, although steadily falling into disuse.] Stocker[1] of Lucerne has resorted to Alexander's operation 37 times during the past 2 years—1. In 22 cases with mobile retroversions or retroflexions; 2. In 10 cases with retroversion complicated by slight uterine fixation; 3. For prolapse as a single operation in 2 cases; 4. For prolapsus uteri combined with perineorrhaphy in 3 cases. The cases in which the backward-displaced uterus was mobile gave excellent results. With partial fixation of the uterus a recurrence took place in 3 cases. In the other 7 cases the adhesions were more marked and could not be ignored; 2 of these did well. The 5 others were treated by a combined Schultz-Alexander operation, and resulted in a good but somewhat fixed anteversion. The 3 cases in which a combined perineorrhaphy and Alexander's operation was performed gave good results. At intervals of 6 months, a year, and 18 months after operation, respectively, each showed the uterus in place and anteverted. Stocker concludes that Alexander's operation, of all operative procedures, restores the uterus to its normal physiologic position and is attended with no danger.

Mundé,[2] the first to do Alexander's operation in this country, as the result of his experience in 97 cases with 87 permanently cured gives the following clearly drawn indications: 1. Retroversion or retroflexion of the uterus of long standing, in which pessaries either do not maintain the uterus in position, are not retained, or cause pain. 2. Retroversion or retroflexion of long standing, associated with relaxation of the uterine supports (ligaments, pelvic floor,

[1] Cor.-Bl. f. schweiz. Aerzte, Dec. 15, 1895. [2] Med. News, Mar. 14, 1896.

and vaginal walls), and consequent greater or lesser *descensus uteri.* 3. *Prolapsus uteri et vaginæ,* in which the Alexander operation is preceded at the same sitting by trachelorrhaphy or amputation of the cervix, and is followed by anterior and posterior kolporrhaphy and perineorrhaphy. 4. The desire of the patient to be *cured* of her displacement—a wish which no pessary or other nonoperative treatment can fulfil. 5. The necessity for keeping the uterus in its normal anteverted and elevated position after the adherent fundus and appendages have been loosened and restored to their normal mobility, either by bimanual tearing of the adhesions or by peeling the organs loose with the fingers through an incision in the posterior vaginal pouch and Douglas's culdesac.

The *contraindications* to the operation are: 1. Adhesion of the uterus or of the appendages. 2. The possibility of retaining the uterus and appendages in a normal position, and of making the patient perfectly comfortable with a pessary, unless, of course, the patient insists on a *cure,* as already mentioned. 3. *Prolapsus uteri et vaginæ,* unless the plastic operations referred to (anterior and posterior kolporrhaphy and perineorrhaphy, and reduction of the weight of the uterus by trachelorrhaphy or amputation of the cervix) are performed at the same sitting.

H. T. Byford[1] says: In cases without adhesions in which we can replace the uterus Alexander's operation affords brilliant results in competent hands, even when the ligaments are small or cannot be found by the novice. In cases of retroversion with adhesions and decided symptoms it is necessary to open the abdomen to separate the adherent surfaces, and it is then simpler, and perhaps safer, to stitch the fundus forward. In cases of retroversion without adhesion and in connection with sterility, or in cases after the change of life and in which other operations upon the vagina are undertaken, vaginal fixation is often the quickest and easiest procedure, and will undoubtedly find a small place in gynecologic surgery. With regard to pessaries, these are useful in cases of retroversion with adhesions in which the uterine pathologic conditions may be expected to subside within a reasonable time, and it will then make but little difference whether the uterus is retroverted or not. [This statement is open to very serious criticism, since retroversion at any age and under any circumstances is productive of the most distressing train of clinical manifestations.]

In cases of **adherent retroposed uteri** Pryor[2] operates from the vagina. The uterus is thoroughly curetted, and, if there be hypertrophy of the cervix, Schröder's amputation is also done. Douglas's culdesac is then opened, and existing adhesions are broken up by the fingers. A large iodoformized pad, to which is attached a string, is introduced into the pelvis and the patient thrown into Trendelenburg's position; the intestines gravitate into the abdominal cavity, and another pad, similar to the first one, is introduced. The table is then lowered, and the uterus is pushed up behind the symphysis by the Péan trowel. The adnexa may then be examined; the uterus is packed

[1] Medicine, Feb., 1896.

[2] Med. Rec., July 20, 1895.

with iodoform-gauze; the pads in the pelvis are withdrawn, and a wad of iodoform-gauze inserted into the vaginal opening *just within the cut edges*; the vagina is packed. The lower pieces of gauze are changed on the third day, and the uterine gauze also; the wad of gauze in the culdesac is not disturbed for from 7 to 10 days. The vagina is kept packed to support the uterus for a month. A similar procedure is recommended by Tucker.[1] [These operations are open to the objections common to all forms of major vaginal surgery, repeated mention of which has already been made in these pages.]

Anterior kolpotomy (anterior kolpohysteropexy) is regarded by Madlener[2] as the most important of recent gynecologic operations: it is of service in retrodisplacements of the uterus and also in removing the appendages. Its introduction and popularity are associated with the names of Doyen, Sänger, Zweifel, Mackenrodt, and Dührssen, the last-named having done most to perfect the technic. Anterior kolpotomy is really the name of a group of operations that have in common the incision of the anterior vaginal wall, either transverse or sagittal, and the separation of the bladder from the anterior uterine wall and access to the peritoneal cavity. The opening of the peritoneal cavity is not necessary in every case. The peritoneal fold between the uterus and bladder reaches to a lower point in some patients than in others. In some it descends to a level with the internal os uteri, and in others to a point higher up. Most operators open the peritoneal cavity in performing vaginofixation. By this method (vaginal celiotomy) the fundus may be drawn into the incision between the bladder and uterus, and the ovaries and tubes brought into view. Madlener has operated by this method 43 times, with satisfactory results in every case. The sagittal incision was used in all but 2 cases; the advantages claimed for this method are that the hemorrhage is less and more room is made than by the transverse incision. He used this method 18 times in movable retrodisplacements of the uterus; in 4 of these cases there was vaginal prolapse, and in 1 case there was total prolapse of the uterus; 7 times in retroversion with adhesions, 13 times for retrodisplacements with diseased ovaries and tubes, and 4 times for uterine myomata. Of the last 41 abdominal sections performed for the removal of diseased appendages, 14 were suppurative. Of this number, about one-sixth might have been done by kolpotomy. It is claimed that this operation gives access to the pelvic organs by a way less dangerous than by abdominal section, thus facilitating intraperitoneal operations. There is an absolute certainty of no hernia. Werder[3] remarks that the indications for vaginal celiotomy or the intraperitoneal methods of vaginal fixation may be placed on the same level with ventrofixation. Its advantages, he says, over the latter operation are the avoidance of an external incision, less danger of septic infection (?), shorter and smoother convalescence, fewer sequelæ, and absence of the distressing symptoms noted after abdominal section (intense thirst and flatulence). The only contraindication to the operation is a very narrow vagina.

[1] N. Y. Polyclinic, vol. vi. No. 5, p. 338. [2] Münch. med. Woch., Nov. 5, 1895.
[3] Jour. Am. Med. Assoc., Aug. 24, 1895.

Wendeler[1] in reporting upon anterior kolpotomy and its results in A. Martin's clinic gives the operative technic as follows: The patient is placed in the dorsal position with the legs raised on either side. A speculum being introduced, the uterus is fixed with a pair of Orthmann's forceps, a combination of uterine probe and volsella, which grasps the anterior lip of the cervix, so that it can be drawn to the vaginal introitus. Another pair of volsella forceps is fastened just under the orifice of the urethra about 3 in. from the cervical opening. The anterior vaginal wall is pulled upward; a fold is raised which is incised vertically and peeled off laterally from the surface of the bladder and cervical body. Hard fibers will be seen above the vaginal insertion, and these are to be divided. The upper border is then pushed upward, separating the loose tissue between the bladder and uterus, thus carrying the former out of the way. The peritoneum is found as a fold between the bladder and the uterus; this is to be opened, when the abdominal cavity and contents are exposed to view. Further operative procedures are to be carried on according to the requirements of the case. Myomatous tumors can be removed, wherever they are situated, by simple excision or by morcellement. Movable retroflexed uteri can be easily replaced, and retained by vaginal fixation. Peritoneal adhesions fixing the uterus are broken up by the finger. Cystic ovarian tumors can be opened and brought outside, so as to expose the pedicle for proper ligation. When the uterus is drawn downward and forward the ovaries and tubes follow as soon as they are freed from adhesions. Anterior kolpotomy, he claims, offers great advantages in treating diseases of the tubes. The uterus and adnexa are to be replaced in the abdominal cavity by pressing on the anterior uterine surface. A strong catgut suture is to be carried with a curved needle through the upper end of the vaginal wound, the cellular tissue at the base of the bladder, the peritoneum, and the anterior uterine wall near the fundus, taking a good hold of it, and out again at the opposite side, and tied. Two other sutures close the vaginal wound, connecting it with the anterior surface of the corpus uteri, and a fourth to the cervix. A running catgut suture is used to close the vaginal wound more exactly. After this method 149 operations were performed; 93 cases suffered from chronic pelvic peritonitis, and in 58 of these the uterus was fixed. Uterine myomata were present in 13 cases, diseases of the adnexa in 18 cases, and other abnormalities of the internal genitalia in 25 cases. During 3 operations the bladder was accidentally injured, each case healing without any disturbance. Secondary hemorrhage was observed 7 times, but the recovery continued uninterrupted. An examination of 87 cases showed complete recovery in all except 9 cases. Wendeler considers the dangers from succeeding pregnancy as trifling if the uterine sutures are placed about 2 cm. below the summit of the fundus.

Vaginofixation still claims some adherents, although Mackenrodt,[2] in consequence of the unfortunate results which have followed pregnancy after vaginofixation, has been led to abandon the operation, in spite of his having

[1] Berl. klin. Woch., No. 2, 1896.

[2] Centralbl. f. Gynäk., 1895, No. 49.

had 90% of successful cases. The uterus is retained in a position of extreme anteflexion by firm adhesions, which do not yield under the influence of pregnancy. He now opens the anterior vaginal fornix by a vertical or transverse incision, pushes up the bladder, opens the vesicouterine fold of peritoneum, and, after excising as much of this membrane as possible, unites the vesical edge to the fundus uteri. The bladder is then reunited to the raw surface in the corpus uteri as low as the os internum, and the vaginal wound is closed. The advantages claimed for this method are fixation of the uterus in a normal position, obliteration of the vesicouterine pouch, preservation of the normal relations of the bladder, and the absence of subsequent vesical and uterine disturbances. The indications for the operation are retroflexion with perfect mobility of the uterus, with or without prolapsus. Ventrofixation should be preferred if the uterus is adherent. Gilbert[1] calls attention to the fact that the operation is not applicable to cases in which it would be necessary to separate firm and extensive adhesions before replacing the uterus; in these cases ventrofixation is indicated. Wertheim[2] asserts that the peritoneal cavity should be opened in every instance, as only in this way is the operation rendered absolutely safe. The criticism that the uterus is fixed in extreme anteversion does not hold, he thinks, as the organ eventually regains its normal mobility. Vesical disturbances, especially from buried sutures, are avoided by using catgut for peritoneal fixation. Vineberg,[3] in order to avoid dystocia after ventral fixation, has devised a new method of performing vaginal fixation, in which, after the usual vaginal incision, the uterus is fixed by Olshausen's method (suturing the round ligaments and a portion of the broad ligament instead of the uterine fundus). The ultimate results are not stated. Byford[4] does the same operation, but includes fixation of the fundus uteri, since he believes that the peritoneal adhesions alone will not suffice to hold the uterus in place. Jacobs[5] punctured the bladder in performing vaginal fixation; and this is one of the possible accidents of the operation. Vineberg[6] has performed vaginofixation 48 times. In the last 28 cases the percentage of cures was 100.

Vineberg,[7] who is an enthusiastic advocate of this operation, records 48 cases in which he has employed it with 8 relapses. Four subsequently became pregnant; 1 induced abortion; 2 went to full term and had easy labors. A vertical incision is first made through the mucosa in the median line from the vesical neck to the cervix. The bladder is then separated transversely with the finger from the uterus until the peritoneum is reached. After the peritoneal fold has either been torn through with the finger or cut with the scissors, the volsellæ applied to the cervix to draw it to the vulva are then made to push it backward into the posterior fornix of the vagina. This step at once throws the body somewhat forward. Then, either with successive volsellæ or

[7] Ibid.

traction-sutures (preferably the latter, as they are not so likely to tear out), he proceeds up the anterior surface of the uterus until the fundus is reached, and it is brought entirely through the vaginal incision. The whole uterus now presents at the vulvar opening. Its anterior and posterior surfaces are rapidly scanned for any pathologic growth. Then with two fingers the adnexa of one side are brought out through the incision. The ease or difficulty attending this procedure depends upon the extent and firmness of the adhesions existing between the adnexa and the pelvic wall and floor. After they are drawn out they can be treated on conservative surgical principles, with the same facility as by the abdominal route. When the tube and ovary are hopelessly diseased, they are tied, as in the abdominal method, and ablated. The tube and ovary of the other side are then drawn out and treated in the same manner. Two or 3 silk sutures are then carried across the anterior surface of the uterus about a centimeter apart, the superior one being passed about 1 cm. below the level of the insertion of the tubes. The next step consists in returning the uterus (the adnexa having been returned before) into the pelvic cavity. This may sometimes be accompanied by considerable difficulty, but is aided by catching the cervix with a volsella and drawing it forcibly into the position in which it was held at the beginning of the operation, by pressing the fundus with the fingers backward and downward. The fixation-sutures are next carried through the vaginal flaps by means of a carrying suture. Before this, however, the anterior surface of the uterus between the sutures has been scarified as in ventrofixation. [This step is the most obnoxious feature in any form of vaginofixation, resulting as it of necessity must in such firm union between the uterus and tissues in front of that organ that vesical symptoms and gestational troubles almost invariably follow.] The same author[1] believes that vaginofixation is indicated in all backward displacements of the uterus, with or without adhesions and with or without diseases of the adnexa, in which surgical interference, for one reason or another, is demanded. It is particularly indicated, he claims, when the backward displacement is complicated by moderate prolapsus of the uterus and prolapsus of the anterior vaginal wall. It finds an undisputed field in very fat subjects with thick abdominal walls, in whom a ventral fixation constitutes a serious affair, and in whom an Alexander operation is extremely difficult of accomplishment. The same holds good in very thin subjects with thin and yielding abdominal parietes, so far, at least, as ventral fixation is concerned. The operation can be performed in multiparæ and even in virgins. It is contraindicated in certain cases of congenital retroversion. It should not be undertaken until a certain period has elapsed after the puerperal process, as the soft and friable condition of the uterus may lead to undesirable laceration in the necessary manipulations to bring about anteversion of the organ. He urges that not enough stress has been laid on the large percentage of failures and the mortality following Alexander's operation, or upon the frequency with which it was followed by hernia.

In a paper read by Dührssen[2] at a meeting of the Berlin Gynecological

[1] Med. News, Mar. 14, 1896.

[2] Centralbl. f. Gynäk., No. 7, 1896.

Society, Jan. 10, 1896, the author points out the objections to the method of intraperitoneal ventrofixation in which the whole anterior uterine wall is sutured to a longitudinal incision in the anterior fornix vaginæ. Instead of this, he advocates a transverse incision, to which he sutures the plica vesicæ, while the uterus is united to the peritoneum of the plica. By this method the uterus, although only fixed by peritoneal adhesions, remains in a normal position and retains almost normal mobility. The dislocation of the bladder consists in a slight anterior displacement. A kinking of the Fallopian tubes does not occur: this is proved by the numerous subsequent pregnancies. Dührssen observed after vaginofixation without opening of the peritoneum 28 pregnancies and 17 normal confinements. These cases prior to operation were either sterile or had repeated miscarriages. He knows of 17 pregnancies following *intraperitoneal vaginofixation;* of these, 1 woman aborted spontaneously, while in another case pregnancy was artificially interrupted; 7 women were delivered at term without aid, and in 4 others labor was complicated. One of these cases has been reported by Strassmann; in this case the union between uterus and vagina, a result of faulty technic, was abnormally firm. In a second case the forceps was applied on account of insufficient dilatation. It is questionable whether this was the fault of the vaginofixation. The 2 remaining cases necessitated version, because the os was high above the innominate line and did not dilate. This complication has also been observed after ventrofixation, and can be avoided by obtaining only a peritoneal union between the plica vesicæ and the uterus. If the os does not dilate in spite of good pains, dilatation with the colpeurynter and combined version are indicated. *In exceptional cases vaginal Cesarean section must be performed*, the technic of which consists of a T-shaped incision into the anterior fornix of the vagina, separation of the vagina from the bladder and of the bladder from the cervix; next the plica vesicæ is pushed upward and the cervix and corpus uteri are divided sufficiently to permit of the extraction of the child. The wounds are afterward united. [In these grave circumstances Cesarean section performed in the usual manner is much to be preferred to the foregoing suggestion, both on account of the ease and rapidity of performance and because of the diminished risk of sepsis.] Dührssen has performed 148 intraperitoneal vaginofixations, with only 1 death and 1 relapse.

Literature is accumulating as to the ultimate outcome of **hysteropexy.** Mackenrodt[1] was compelled to remove the uterus from a woman who had undergone hysteropexy for prolapse about a year previously. Dragging and tearing pains were felt constantly, being referred to the site of adhesion of the fundus to the parietes, and the patient became more of an invalid than before the operation; hence the necessity for the excision of the organ. Baldy[2] also was compelled to perform hysterectomy on a patient upon whom hysteropexy had been performed 1 year previously. Garceau[3] reports a fatal case of pulmonary infarction occurring 6 days after hysteropexy, with thrombosis of the

[1] Centralbl. f. Gynäk., No. 28, 1895. [2] Am. Jour. Obst., vol. xxxiii. No. 4, 1896.
[3] Boston M. and S. Jour., Dec. 19, 1895.

left iliac vein. Goubaroff[1] was compelled to deliver by Cesarean section a patient on whom Küstner had performed hysteropexy 4 years previously. The abdominal cicatrix was found closely adherent to the anterior surface of the uterus, which bore a depression on its fundus. The cervix was so high up that it could not be reached without the aid of anesthesia. The upper part of the vagina was contracted and the os completely closed. The left shoulder presented. As a rule, it is claimed that hysteropexy adhesions break down during pregnancy. Kelly[2] in an article based on a series of 200 operations states that there have been at least 6 pregnancies, in only 1 of which was there any marked discomfort and dragging due to the attachments of the womb. Baldy[3] cites 2 cases, both having easy confinements. Gottschalk[4] mentions 2 cases in which the pain was unduly severe. Mackenrodt[5] reports a case of difficult labor, and Michaelis[6] 1 case.

Léon[7] writes that the results of abdominal hysteropexy as shown in the paper published by Laroyenne—namely, that pregnancy occurring after this operation is usually followed by abortion—are due to faulty technic in the method of placing the sutures between the abdominal wall and the uterus. Léon gives the following rules to be observed in this operation: 1. The sutures should not be removed; 2. The number of sutures should be sufficient; 3. The sutures should be placed through the anterior wall of the uterus and not the fundus; 4. The sutures should include sufficient tissue, at least 0.5 cm. From the observations of Laroyenne and the greater number of French surgeons the adopted technic of the operation does not allow the physiologic growth of the uterus during pregnancy, and, besides, the adhesions are not firm enough. Of 60 cases operated upon by Laroyenne, 3 became pregnant; of these 1 proceeded to full term and 2 aborted in the first month. The writer believes that abortion in these cases was induced early in pregnancy because the fundus and not the anterior uterine wall was sutured. [The author is undoubtedly correct in ascribing the troubles noted after hysteropexy largely to some defect in technic. The proper operation is a *suspension* of the uterus by the peritoneal covering of the fundus, and not a true and firm fixation of that organ to the anterior abdominal wall.]

Edebohls,[8] from a study of ventral fixation concludes that—1. Vaginal fixation does not come within the sphere of legitimate operations in women liable to future pregnancy. 2. The indications for ventral fixation of the uterus should be limited to the utmost degree in women liable to subsequent pregnancy. 3. Ventral fixation is never indicated in uncomplicated retroversion of the uterus. 4. Inability of an operator to perform shortening of the round ligaments *may* be an indication for ventral fixation, but not in the case of one claiming to be a specialist in gynecology. 5. Ventral fixation is indicated, *as an adjuvant*, in the performance of combined operations for pro-

lapsus uteri et vaginæ. 6. Ventral fixation is indicated as a closing step in all abdominal sections in which the adnexa are removed and the uterus is left. 7. Ventral fixation *may* be indicated, under exceptional conditions, in cases of adherent retroversion with tubes and ovaries in good condition. 8. Ventral fixation *may* be indicated in the most aggravated cases of uncomplicated sharp retroflexion: the writer has not met such a case not amenable to successful treatment by shortening the round ligaments. 9. Ventral fixation is indicated, under certain conditions, in cases of uterus unicornis. Leopold,[1] during a discussion at the Dresden Gynecological Society, took occasion to criticise vaginofixation of the uterus, and instead recommends ventrofixation. He performed the latter operation in 73 cases, and has never seen serious complications during pregnancy or labor. The evil results observed after ventrofixation he ascribes to faulty technic and a fixation of the uterus at the level of the umbilicus or immediately above the bladder, or that the fundus plus posterior uterine wall was fixed to the abdomen, or that the sutures consisted of nonabsorbable material. The proper technic consists in fixing the uterus about 1 in. above the symphysis, and the sutures, two in number, should be passed through the anterior and upper portion of the corpus uteri. Leopold also performed 8 Alexander operations, and, although he experienced no difficulty in finding the round ligaments and placing the uterus in a normal position, he found that the patients frequently complained of pain in walking and in the inguinal canal, and he also observed that the healing of the wounds was often protracted.

In comparing ventrofixation and Alexander's operation Smith[2] remarks that the former has some great advantages—namely, it can be employed in cases in which the ovaries and tubes are adherent; also, patients complain of pain and numbness of the groin and labia after Alexander's operation, due to the severing of the nerve running along the round ligament, which is not noted after ventrofixation.

Fowler[3] suggests a new method of performing hysterorrhaphy, in which the uterus is secured to the anterior abdominal wall by means of the urachus. The superior ligament of the bladder extends from its summit to the umbilicus and encloses the obliterated urachus and hypogastric vessels. It is narrowest at the umbilicus. The usual abdominal incision is made and the urachus identified; its upper extremity is cut across, and the cord, together with a ribbon of peritoneum 1 cm. wide, is detached down to the level of the lower angle of the wound. The uterus is next brought into position, and a Cleveland ligature-carrier is passed beneath its serous and subserous coats at a point on its posterior wall near the junction of fundus and posterior wall. The ribbon of peritoneum and urachus is then drawn into the opening, where it remains fixed; the portion over and above what is required is restored to its normal position and secured by stitches. The operation is quickly performed.

FIBROID TUMOR OF THE UTERUS.

Borissoff[1] has made investigations upon 21 uteri in order to ascertain, if possible, the cause of the frequent and obstinate **hemorrhages that are associated with fibroid tumors.** Wyder in 1878 first announced that the endometrium was converted into diffuse adenoma, and in 1887 he reported 20 cases in which he found interstitial endometritis. Campe found in 10 cases chronic glandular endometritis with inflammatory changes in the stroma-tissue in 1 case. Schmal in 1891, from the investigation of 15 cases, concluded that atrophy of the endometrium occurred over the tumor and hypertrophy distant from the tumor. Finally, Semb, with 23 cases, stated that no definitely characteristic changes could be determined. The results of Borissoff's microscopic examinations were as follows: In the endometrium removed from the site of the tumor there was atrophy with complete or partial destruction of the glands in 11, glandular endometritis in 3, interstitial endometritis in 5, and glandular and interstitial endometritis associated in 2 instances. In 13 uteri it was possible to remove a portion of the tumor-wall with the endometrium. In these sections an atrophic change was seen in 7, glandular endometritis not at all, interstitial endometritis in 3, and glandular and interstitial endometritis in 3 cases. The most pronounced change was always seen in those cases in which there was an interstitial tumor. In 2 cases of subperitoneal tumor the entire endometrium had atrophied, and in another there was glandular and interstitial endometritis. In many of the preparations every form of endometritis was to be seen. As regards the hemorrhage, the following order was observed: Where there was menorrhagia, 2 cases, glandular endometritis was found in 1, and glandular and interstitial endometritis in the other. Where there was metrorrhagia, 11 cases, atrophy of the endometrium was found in 7, glandular endometritis in 1, interstitial endometritis with beginning sclerotic change in 2, and glandular and interstitial endometritis in 1. It was particularly noticed in the greater number of microscopic sections that beneath the superficial portions of the endometrium the blood-vessels were very much dilated and filled with corpuscles. This condition extended to the surface, where there was an atrophic change. Besides this, a diffuse extravasation of blood was seen in all sections, most marked in the superficial endometrium, but sometimes extending into the muscular wall. In most of the sections the superficial epithelial cells had disappeared. Borissoff concludes that the hemorrhage results as follows: When the tumor reaches a palpable size a hyperemia of the uterine body occurs that sometimes results in a parenchymatous inflammation not unlike that seen in the ovary as described by Popoff and others. This first causes the menorrhagia that usually appears before the tumor is diagnosed. As the tumor increases in size the circulation is more and more obstructed in the uterine wall and endometrium, as shown in the description of the microscopic sections. Under the influence of the circulatory obstruction the menorrhagia becomes progressively more profuse and persistent. As

[1] Monatsh. f. Geburtsh. u. Gynäk., 1895, B. ii. H. 5.

a further result of the obstruction the blood-vessels undergo structural change because of the increased blood-pressure or fatty degeneration, and they rupture. At this time the hemorrhages become most frequent, persistent, and severe, often requiring treatment. The extravasation of blood from the overfilled or degenerated blood-vessels of the endometrium causes the destruction of the superficial endometrium and allows the blood to escape into the uterine cavity. The extravasation of blood also explains the blood-tinged watery discharge so often seen. The increased size of the uterine cavity, necessitating a wider area of diseased endometrium, also helps to explain the hemorrhage. Why it is that in a few cases of interstitial fibroid tumor the menstrual flow is normal or absent is difficult to determine. Borissoff believes there is here some associated condition preventing hemorrhage, as disease of the ovaries, general anemia, insufficient circulatory development, or a misplaced uterus.

Ott[1] has operated upon a woman 34 years of age, whose ovaries Lebedeff had removed 3 years previously for a retrocervical fibroid. After temporary atrophy the tumor grew larger than ever, and caused acute pain. On opening the abdominal cavity Ott found the uterus as high as the umbilicus on the top of a large and entirely subperitoneal tumor. The uterus was removed first, then the tumor, the latter operation proving very difficult. Compression of the aorta and plugging of the capsule, which was fixed to the abdominal wound, checked the hemorrhage. The capsule suppurated, but the patient recovered for a while, a fistulous track remaining. Bad symptoms set in again, and a soft mass was detected at the bottom of the fistula, which on microscopic examination was found to be sarcomatous, though the large tumor seemed an ordinary fibroid. The malignant deposit speedily became diffused. In a second case a large uterine fibroid was removed, but a mass which seemed simply fatty was left in the broad ligament. On cutting into the fibroid after its amputation a sarcomatous mass was discovered in its interior. Ott observes that the diagnosis of *sarcomatous degeneration of a uterine fibroid* is not easy; the condition may even be overlooked at the time of operation.

Ricker[2] has made researches in order to throw light on the true origin of uterine fibroids. He does not support the opinion of Kleinwächter and others that the muscle-cells in a myoma were originally discarded, so to speak, from arterioles subsequently blocked. There is strong reason to believe that myoma has usually an embryonic origin. In certain cases very distinct epithelial relics are found in myoma. These seem to represent remains of the primitive epithelium of Müller's duct. Relics of the Wolffian duct are decidedly to be found in the uterine wall; in fact, Ricker seems as certain as Coblenz as to the persistence of this duct and its relation to new growths. Abnormal ingrowths of muscle-cells around the duct are represented in Ricker's drawings. Hence it is probable that every myoma originally arises from some abnormal growth of muscle around the Wolffian duct in the uterine wall or around epithelial débris from the Müllerian duct-relics, which may even be

[1] Ann. de Gynéc. et d'Obstét., Dec., 1895.

[2] Virchow's Archiv, vol. cxlii. part 2, Nov., 1895.

distinct diverticula not entirely effaced after the fusion of that duct with its fellow to form the uterus. Ricker notes that, on *a priori* reasoning, carcinomatous changes in a myoma ought not to be rare, since epithelial elements originally form an essential part of that new growth. Yet he admits that not a single authentic case of carcinomatous degeneration of a myoma has ever been recorded. Sarcomatous changes have been detected by good authorities, but so rarely that a uterine "fibroid" is practically as innocent as a true fibroma developed in any part of the body.

Treatment of Fibroid Tumors.—The operation of Gottschalk and Martin has not given brilliant results. Kuhn[1] states that in 6 operations by Howitz only 1 was successful, on account of the youth of the patients and the size of the tumors. The operation, it must be admitted, is attended with but a minimum of danger, but its application is limited to tumors that are soft, bleeding, and of minimum size. It is not applicable to very large, hard tumors, to those that are within the broad ligament, nor to those that are of considerable size.

[Battey's operation is still of service in a certain proportion of cases, and when other more radical procedures are not permitted it may prove beneficial, provided there do not exist any contraindication to its performance. It is, however, an operation that is rarely performed.] Johnson[2] has performed the operation in 34 instances for fibroid tumors, and all but 1 of the cases have been successful, so far as arrest of hemorrhage and cessation of growth were concerned. Dorland has done the operation in 1 case within the year, with the result of arresting the growth of the tumor, but not completely checking the hemorrhage. Recent investigations have shown that the menopause, either normal or induced, has not such a decided influence upon these tumors as was formerly believed. Johnson[3] believes that the average failures of the operation amount to about 10%.

Obalinski[4] of Warsaw considers the enucleation of the fibroid growth with conservation of the uterus as the ideal method. He recommends a new method of operating, which he terms *organo-pexil.* His technic is as follows: When the tumor is pedunculated the pedicle is cut in the form of a cone, and the peritoneal flaps thus formed are united by a suture. When the growth is interstitial he makes a longitudinal incision in the wall of the uterus and extirpates it bluntly with the finger and handle of the scalpel. The blood-vessels are caught and tied. The uterine wound is sutured at its depth, and is then sewn to the abdominal wound. Several strips of gauze are passed in the lower angle of the wound down to the uterus, the wound of the abdominal incision being closed in the usual way. He has operated in this way in 4 cases with complete success.

As to the relative value of supravaginal hysterectomy and complete or total removal of the uterus opinions differ. Ashton[5] remarks that the selec-

[1] Nordiskt med. Arkiv., Aug., 1895.
[2] Va. Med. Monthly, Jan., 1896.
[3] Loc. cit.
[4] Przeglad Chirurgiczny, tome 2, zezeit 2, 1894.
[5] N. Y. Med. Jour., Feb. 1, 1896.

tion of either one of these operations depends upon the indications in a given case. For example, total hysterectomy is indicated in sloughing fibroids with general infection of the uterus, or when malignant disease is associated with the neoplasm. On the other hand, supravaginal hysterectomy is the preferable operation when these conditions are absent, since it is impossible to render the vagina aseptic; and, again, the vaginal vault is better preserved when the cervix is left intact, and thereby sexual intercourse is not interfered with.

Removal of the uterus and appendages by continuous incision, as first proposed by Pryor several years ago, has been done by Kelly[1] in upward of 200 cases. The operation consists in the following steps: 1. Opening the abdomen. 2. Ligation of the ovarian vessels near the pelvic brim, either on the right or on the left side, clamping them toward the uterus, and cutting between. 3. Ligating the round ligament of the same side near the uterus, cutting it free, and connecting the two incisions, in order to open up the top of the broad ligament. 4. Incision through the vesicouterine peritoneum from the severed round ligament across to its fellow, freeing the bladder, which is now pushed down with a sponge, so as to expose the supravaginal cervix. 5. Pulling the body of the uterus to the opposite side to expose the uterine artery low down on the side opened up. The vaginal portion of the cervix is located with thumb and forefinger, and the uterine artery, seen or felt, is tied just where it leaves the uterus: it is not always necessary to tie the veins. 6. The cervix is now cut completely across just above the vaginal vault, severing the body of the uterus from the cervical stump, which is left below to close the vault. 7. As the last fibers of the cervix are severed or pulled apart, while the body of the uterus is being drawn up and rolled out in the opposite direction, the other uterine artery comes into view and is caught with artery-forceps about an inch above the cervical stump. 8. Rolling the uterine body still farther out, the right round ligament is clamped and cut off, and lastly the ovarian vessels are clamped at the pelvic brim, and the removal of the whole mass, consisting of uterus, tubes, and ovaries, is completed. 9. Ligatures are now applied in place of the forceps, holding the uterine artery, round ligaments, and ovarian vessels; if the surgeon prefers, these may be tied as they are exposed without using forceps. 10. After the enucleation the operation is finished in the usual way, (*a*) by closing the cervical tissue over the cervical canal, and then (*b*) by drawing the peritoneum of the anterior part of the pelvis (vesical peritoneum and anterior layers of the broad ligaments) over the entire wound-area and attaching it to the posterior peritoneum by a continuous catgut suture. The continuous transverse incision should always be started on the side where the ovarian vessels and the ovary and tube are most accessible. If the case is one of a fibroid uterus and the tumors are developed under the pelvic peritoneum or in the broad ligament of one side, this side should be opened up last, from below upward, when the tumors can be rolled up and out with surprising facility. Displaced ureters

[1] Johns Hopkins Bull., Nos. 59, 60.

will not be injured, for on the side on which the enucleation is started such a ureter is pushed down with the loose peritoneum as the uterus and tumors are pulled up and toward the opposite side, and on the other side, no matter how much the ureter is displaced out of the pelvis, as the tumors caught from below are rolled up and out the ureter drops down with the peritoneum and cellular tissue to the pelvic floor, and the operator need not even see it or be aware of its displacement to avoid the risk of injuring it. If the ureter is found to be displaced only on one side, the operation should begin on the opposite side. To escape the danger of tying the ureter in the side on which the uterine artery is caught after dividing the cervix, put the forceps on the artery well above the cervical stump and tie there. The special advantages offered by this method are—1. The saving of from 60 to 80% of the time in the enucleating stage of the operation. 2. The ease with which intraligamentous myomata and myomata beneath the pelvic peritoneum may be enucleated. 3. The ease with which inflammatory masses posterior to the broad ligament may be enucleated by attacking them from below after dividing the cervix. 4. The control of a displaced ureter on the side last opened up, keeping it out of the way of injury by the simple mechanism of the operation. [In unskilled hands the operation is an exceedingly dangerous one and should only be resorted to in the case of intraligamentous fibroid tumors, as was originally done by Pryor, or in very bad pelvic inflammatory cases where the broad ligaments are practically obliterated by the inflammatory products. It should remain most decidedly the method of necessity, not of choice.]

Vaginal Hysterectomy.—Papers on vaginal hysterectomy for pyosalpinx and uterine myomata have been presented by Wathen,[1] Irish,[2] Cushing,[3] and Donald.[4] Irish writes to favor the operation only in cases of extensive pelvic abscess—that is, when the pus is more or less diffuse in the pelvis. In his experience the after-results in patients operated upon by the abdominal method are much superior to those in patients subjected to the vaginal incision; there has been less disturbance, and recovery has been as rapid as after the vaginal method. When clamps are used there is often noted, he claims, abdominal distention and reversed peristalsis, indicating a localized sepsis. Also, the tissue caught in the blades of clamps must slough and come away—a process often occupying 2 or 3 weeks. Cushing claims that freedom from shock, hernia, and scar is the main advantage of the vaginal route, and he asserts that the method is gaining ground, not only in France, but also in New York, Chicago, Pittsburg, and Boston. The disadvantages are the greater amount of skill required and the larger number of instruments needed. He claims that adhesions can be much more readily overcome from below than from above, and, if need be, a little of the uterus may be snipped off and left attached to the bowel; which cannot be done from above unless hysterectomy is to be performed. As to the method of performing *morcellation*, there are three principal ways—Péan's, Müller-Quénu's, and Doyen's.

[1] Am. Jour. Obst., Aug., 1895.
[2] Boston M. and S. Jour., Jan. 23, 1896.
[3] Ibid., Jan. 23, 1896.
[4] Brit. Med. Jour., Feb. 29, 1896.

Péan's original operation is as follows: He makes a circular incision around the cervix, separates the bladder anteriorly and the rectum posteriorly from the uterus, and clamps the lower part of each broad ligament; then he splits up the uterus on each side, and, grasping the anterior portions high up with forceps, he cuts the posterior flap away. When this is removed the uterus can be made to roll a little forward. The bladder may then be dissected away and the anterior culdesac opened; then a narrow speculum, bent at a right angle, is put in, and lifts the bladder out of the way. The operator then cuts off the anterior flap, and pulls it down with forceps on each side of the stump. Then the whole process is repeated. Each time, before cutting laterally, a clamp is laid on the broad ligament, so that there is no bleeding as the uterus comes down. In difficult cases one cannot always get on in that way, and then comes the principle of splitting the anterior flap vertically in the middle. If the uterus is split in the middle anteriorly after the lower portion has been removed, it comes down very much more. The minute the consistency of the uterus is broken by splitting it, each part will come down separately more than the whole organ would do.

The procedure of Quénu is an amplification of that of Müller, who proceeded years ago to split the uterus and tie each ligament separately. Quénu splits the uterus in the median line anteriorly, and extracts the uterus by getting a new hold with volsella forceps as the uterus comes down. He does not do any lateral division of the uterus, but puts on clamps from below upward, removing the lower portion of the cervix as he proceeds.

Almost all of the other operators put the clamps on as follows: One short pair on each side holds the lower part of the broad ligament and prevents all bleeding. When the uterus is brought outside another clamp from above is put downward, externally to the ovary if possible, so as to meet the first one, and if a little blood comes in the middle, it is easy to put a third clamp on. The process of Doyen is to split the uterus anteriorly, and thus to bring the whole uterus outside before he clamps anything, and then he makes a long clamp and puts it on from above downward, trying to get the broad ligament and round ligament, and leaving the ovary and tube on the uterus above; and to prevent it from slipping off he puts a little clamp on the free end of the stump of the broad ligament.

Abdominal Hysterectomy.—Penrose [1] cites some of the dangers attendant upon the presence of a fibroid tumor, including cystic degeneration, inflammation, associated tubal disease, malignant degeneration, pressure-disease of the urinary organs, and the serious effect upon the heart-muscle, which is often overlooked. He states that every abdominal tumor causes an increased vascular pressure, and consequently reacts upon the heart. Hofmeier in 1884 insisted on the frequency of cardiac disease in cases of abdominal tumor, especially with fibromata. He collected 18 cases in which sudden death occurred from heart-failure. In 3 there was fatty degeneration, and in 15 brown atrophy of the heart. Penrose advises hysterectomy in the vast majority of

[1] Univ. Med. Mag., Jan., 1896.

cases of uterine fibroid. Baldy[1] has noticed that a certain proportion of his cases had a profuse and persistent vaginal discharge during convalescence. In abdominal hysterectomy he sutures with a continuous suture the cut edges of the vaginal mucosa, also the connective tissue and peritoneal edges in the same manner, so that all the wound is extraperitoneal, including the stumps of the uterine arteries. In the past all sutures and ligatures he used were of silk. One patient brought him several pieces of silk passed by the vagina after 3 or 4 months of profuse discharge, after which the discharge rapidly ceased. The silk probably became infected from the vagina, as the same silk used elsewhere in the operation remained sterile. The records of 37 cases show 6 with a prolonged discharge and subsequent throwing off of suture or ligature material, followed by a cessation of the discharge. To obviate this, the suture joining the vaginal mucous membrane might be inserted in such a manner as not to pass entirely through the vagina, and thus avoid infection, or an animal suture, quickly absorbable, would be less liable to become infected on that account, or at least would limit the duration of the discharge. For the above reasons Baldy now uses catgut entirely in hysterectomies, except for the ligation of the uterine and ovarian arteries, where silk is used on account of its strength being more reliable. For $1\frac{1}{2}$ years he has used catgut in all abdominal work without observing a single case of infection. It is easy to make catgut sterile, provided not too much strength is required of it; in trying to retain the strength the sterilization is apt to be sacrificed, and in this sort of catgut the infection is apt to occur. Baldy suggests that a piece of each freshly sterilized batch of gut should be placed in culture-media, and thus its safety positively ascertained. He is positive that by its use his patients have had more certain and less tedious recoveries.

[The question of the treatment of the pedicle in myomohysterectomy is now practically determined. The dropping of the pedicle, with the suturing over it of the peritoneal flaps, thereby practically rendering it extraperitoneal, is now the approved method of treatment. There are many aspirants to the honor of having devised this procedure, but it is probable that the credit belongs largely to Carl Schröder of Berlin, who carried the extraperitoneal treatment of the stump to great perfection in technic. His method has been modified in a vast number of ways, but the idea is the same in all.] Goffe[2] claims for this intrapelvic but extraperitoneal treatment of the stump the following points of superiority: 1. It involves the least possible loss of blood; 2. It is easy of execution; 3. It is applicable to every case of fibroid tumor; 4. It requires less time than total extirpation; 5. Convalescence, as a rule, is rapid and free from complication. He reports 15 cases operated upon by this method, with but 1 death, while J. T. Johnson[3] reports 17 cases, with 1 death. H. Treub[4] has performed 100 myomohysterectomies in which the pedicle was embraced by an elastic ligature and buried. First, the ligaments on both sides were ligated down to the cervix, and then the bladder separated from

the uterus. After cutting away the tumor the cervical canal was mopped with mercuric chlorid solution by means of absorbent cotton and forceps. He has had 7 deaths, most of which could not be attributed to the method employed.

In 204 cases of hysterectomy A. Martin[1] has tied the ureter twice, with fatal result. The bladder was injured in only 2 instances, this being due to the fact that Martin separates it from below upward before opening the anterior vaginal fornix, the procedure being materially assisted by maintaining upward traction on the uterus. He employs the following technic: The vagina is thoroughly cleansed 24 hours before operation, and is tamponed with sublimated gauze. Immediately beforehand it is scrubbed with soap and water, alcohol, and mercuric chlorid solution. The Trendelenburg posture is not used. After opening the abdomen the growth is lifted out *in toto*, traction being assisted by pressure exerted through the vagina if necessary. In some cases it may only be possible after removing some of the smaller tumors. The broad ligaments are ligated in the usual manner with juniper catgut, one side being completely secured before the opposite ligament is ligated. A Richelôt's clamp is applied to the stumps outside of the ligatures. The uterus is then detached as low as the vaginal attachment, and the vagina is opened posteriorly, preferably by boring into it with the end of a dressing-forceps; the edges of the vaginal wall and the peritoneum of Douglas's pouch are then united by interrupted sutures. The bases of the broad ligaments are sutured to the lateral walls of the vagina in the same manner, the cervix meanwhile being drawn upward with a volsella. Finally, the bladder is dissected off from below, the sutures, which have been previously passed through the anterior wall of the vagina and vesicouterine fold, are tied, and the uterus is removed. The ligatures, which are left long, are drawn down into the vagina and the peritoneal flaps are united. Drainage is not employed. The abdominal wound is then closed. The operation is often completed in 30 minutes or less, and the patients' convalescence is uneventful, so that they are usually discharged at the end of 2 weeks.

MALIGNANT DISEASE OF THE UTERUS.

Sarcoma.—Launen[2] describes a case of that rare neoplasm, sarcoma deciduo-cellulare, in which he diagnosticated the condition by the examination of tissue removed with the curet, and extirpated the uterus successfully a few days later. Seven months after the operation the patient was perfectly well, and had gained 20 lb. in weight. This case was the fifth in which a radical operation had been performed, but only the second in which the patient was still living. The diagnosis was made from a history of a previous pregnancy and abortion, irregular hemorrhages, and foul discharge, accompanied with septic symptoms, vomiting, and cachexia. On examining the uterine cavity with the fingers a soft neoplasm could be felt, portions of which were removed and examined microscopically, when the diagnosis was confirmed by finding

[1] Berl. klin. Woch., 1895, No. 29.

[2] Arch. f. Gynäk., Bd. xlviii. H. 3, 1895.

processes of decidual cells which invaded the muscle-fibers, thus proving the malignancy of the growth as well as its decidual origin. He concludes that while one may not succeed in removing a specimen for diagnostic purposes which presents such a typical appearance, the clinical history will at least make it clear that a malignant intrauterine growth exists, and that total extirpation is strongly indicated.

Farron and Vignard[1] record an interesting case of diffuse sarcoma of the uterus occurring in a patient 60 years of age, single, and never pregnant. The woman began menstruating at the age of 13, was regular up to 50, and then irregular; her menses ceased entirely 4 months before being seen for the present condition. Two years before, for a period of about 3 months, she had a profuse watery discharge. The patient's abdomen had increased in size during the last 5 years; she had also lost flesh and strength, and complained of abdominal pain. An examination showed a very large abdomen, almost symmetric and giving the impression of pregnancy. Palpation gave a sensation of sacculated fluctuation. Upon opening the abdomen a rose-colored tumor, almost filling the abdominal cavity, presented itself; it was ovoid in form and free from adhesions. From either side spread two large bands, like wings, which contained the enormously enlarged ovaries and tubes. The tumor, which was evidently the enlarged uterus, was removed *in toto;* it weighed, empty, 9 lb. Microscopic examination showed diffuse sarcomatous degeneration of the uterine mucosa.

Ichthyosis Uteri.—Gautier at the International Medical Convention at Geneva first announced that a condition exists in which the cavity of the uterus is lined with stratified epithelium exactly similar to the epithelial covering of the skin or the vagina. Zeller, however, in 1884 was the first to fully describe this condition under the name of *ichthyosis* or *psoriasis uteri.* Ries[2] claims that, although treated lightly at first, Zeller's paper has gained a very great importance since cases of squamous epithelioma have been observed in the cavity of the uterus. According to generally accepted ideas on the formation of malignant growths, we could not expect to find in the uterine cavity any other kind of carcinoma than that composed of and originating from columnar epithelium. Since Piering first published a case of cancroid of the body of the uterus in 1887 the number of cases has so much increased that gynecologists have had to attribute very grave importance to the occurrence of stratified epithelium on the uterine mucosa. There are however, three conditions in which stratified epithelium is observed at places where we would expect to find the normal columnar epithelium of the cavity of the uterus. Pavement epithelium has been observed by Zeller, Küstner, Ruge, and others on cervical polypi, and by Ruge and Gebhard in inversion of the uterus. Ruge has also seen cases of large procidentia of the uterus with deep tears and ectropion of the cervix, in which he observed stratified epithelium in the lower part of the uterine cavity. In all of these conditions the uterine mucosa is in contact with the vagina and vulva. We may speak of a sort

[1] Arch. prov. de Chir., Dec., 1895.

[2] Am. Gyn. and Obst. Jour., Feb., 1896.

of infection with pavement epithelium brought about by contact with organs covered with the same variety of epithelium. It is impossible at present to determine whether air may exercise some chemical influence, inducing metamorphosis of columnar into stratified epithelium. Veit calls this process "epidermidalization;" Zeller thinks it belongs to the condition described by him as ichthyosis uteri. Zeller has examined 54 cases of chronic endometritis, 51 of them in persons less than 50 years of age. In all of these cases he found the surface of the mucosa of the uterine cavity covered partly or totally with stratified epithelium resembling that of the skin or vagina. The most superficial cells could be stained yellow by picric acid; generally they contained nuclei. The number of layers of flat cells was from 1 to 4. Below this stratified epithelium he always found the glands increased in size and number. The stratified epithelium sometimes filled the mouth of the glands and covered their columnar epithelium. In all cases the stratified epithelium of the surface formed papillæ. Ries has examined microscopically more than 200 cases of uterine scrapings, but in only 1 of them did he find the condition described by Zeller. He also found it in a case of carcinoma of the cervix, in which the stratified epithelium existed as a level covering of the cavity of the uterus. There were no processes of the epithelium penetrating into the subjacent tissue. No traces of uterine glands could be discovered. He regarded this as a case of simple ichthyosis uteri coexisting with carcinoma of the cervix. Gebhard believes that there are two different series of cases with stratified epithelium: the one kind always remains limited to the surface—simple ichthyosis; the other kind has the tendency to penetrate into the subjacent tissue and form cancerous nests. Pfannenstiel says: "Not every case of stratified epithelium in the cavity of the uterus should be indicative of carcinoma, but the stratified epithelium found in the cases of squamous epithelioma of the cavity of the uterus must be considered the preliminary stage of the carcinoma, just as a glandular hypertrophy of the uterine mucosa, nonmalignant in itself, can be the preliminary stage of adenocarcinoma." Ries, therefore, lays down the following rules: The clinical symptoms of ichthyosis are not sufficiently clear to enable us to found a diagnosis on them. Discharge and light hemorrhage, the usual symptoms of ichthyosis, can as well be produced by carcinoma of the body and several other conditions as by ichthyosis. If we scrape out a uterus and examine the scrapings microscopically, we may only find the stratified epithelium. We are then not enabled to give a diagnosis of carcinoma or of ichthyosis, but must reserve our diagnosis if the epithelium itself does not contain some further clues as to the nature of the disease. In other cases the curet procures sufficient tissue for a precise diagnosis. If we find the stratified epithelium limited to the surface or penetrating only into the mouth of the glands, the diagnosis must be ichthyosis. We must, however, always frequently observe these patients for some time, because we do not know if the ichthyosis will not undergo metamorphosis into carcinoma. If, on the contrary, the microscope reveals cords of pavement epithelium penetrating into the tissues of the mucosa or even into the muscular wall

of the uterus, the diagnosis must be one of carcinoma, and speedy removal of the uterus is indicated. Squamous epithelioma of the uterus does not necessarily originate in previous ichthyosis of the uterus, but squamous epithelioma of the cervix may spread over the mucosa of the body, as in cases described by Benckiser and Hofmeier, or the cancroid of the body may be a metastasis of a cancroid of the cervix, as in a case described by Pfannenstiel.

Carcinoma.—Paschen[1] reports a case of carcinoma occurring simultaneously in two portions of the uterus. This is exceedingly rare. Pfannenstiel has collected 9 cases from literature, and has himself added 2. In 3 cases the body of the uterus and the outer part of the cervix were involved, and in 8 cases the body and the cervical canal were simultaneously affected. In 3 cases the pavement epithelium was carcinomatous; in the other cases the columnar epithelium was involved. In all the cases normal tissue existed between the diseased portions. In Paschen's case the woman was 40 years of age, and had had 6 children and 3 miscarriages. Four months previous to operation she had had a severe hemorrhage, and it was then that the diagnosis of carcinoma of the cervix was made. The patient was then attacked with pneumonia, and during this time had several uterine hemorrhages that were controlled by packing the vagina with iodoform-gauze. The uterus was slightly enlarged, but no irregularities could be felt upon its surface. A vaginal hysterectomy was performed, and the patient made an uninterrupted recovery. Upon examining the specimen a large focus of carcinoma was found in the cervix, but it did not reach to the internal os. On the mucosa of the anterior wall of the uterus a carcinomatous nodule the size of a pea was found. In the posterior wall of the uterus a still larger focus was found, and 3 additional nodules were discovered in the region of the right tube. Paschen believes that the disease was primary in the cervix, and the infection of the body the result of metastasis or by direct inoculation.

Pathogenesis of Carcinoma.—W. R. Williams[2] believes that neoplasms are of intrinsic origin, due to a modification of the formative process by abnormal forces generated within the body, rather than extrinsic, due to inflammation or to the intrusion of microorganisms. Whereas Cohnheim considers that the only cells capable of originating neoplasms are those sequestered during embryonic life, Williams holds that new growth may arise wherever undifferentiated cells are present, and are most prone to originate where such cells most abound. Cancerous growths differ morphologically according to the structures whence they originate and which they resemble histologically, as seen in those of the skin, breast, and rectum; while inflammatory pseudoplasms present the same structure independent of their situation. Cancers possess the power of autonomous growth and development, by which they tend to persist and increase indefinitely, but inflammatory processes tend to disappear. The great resemblance between primary and secondary malignant growth is unaccountable as the basis of inflammatory or bacterial origin. Statistics show that in the great majority of cases the origin of carcinoma cannot be attributed to

[1] Cent. f. Gynäk., Oct. 5, 1895.

[2] Med. Chron., Jan., 1896.

the immediate action of any appreciable extrinsic cause, as traumatism or pre-existing disease. In the genesis of neoplasms two factors act: the cells whence they originated and the force regulating the cellular activities. Spencer has shown that we are justified in assuming that every component cell of the multicellular organisms has the power, under favorable conditions, of developing itself into the form of the parental organisms. Contrary to the opinion of Weissmann, who founded his theory of heredity on the assumption that the reproductive properties of somatic and germ cells are fundamentally different, Williams believes that the somatic properties of somatic and germ cells differ only in degree, the reproductive power of the former being seen in the process of repair and various pathologic processes. That the reproductive activity manifested by somatic cells usually falls so far short of their potentiality is believed by Spencer to be due to the restraining and modifying influence exerted by the whole organism on their protoplasm, which is thus compelled to perform other comparatively subordinate modified functions, in doing which most of the protoplasm is metamorphosed and used up, its reproductive function being greatly reduced or lost. In the higher organisms certain cells never become highly developed, but serve, according as they are more or less unspecialized, either for reproducing the entire individual or for forming and maintaining the various tissues and organs. Such cells abound in all parts, and are *the only real cancer- and tumor-germs.* In the ordinary course of organic evolution cell-growths and multiplication go on until the amount of structure proper to the organism has been produced; then they are restricted within certain limits, in the healthy organism, throughout the life of the individual. Herein we have conclusive evidence of a force regulating the growth and development of the tissues and organs in relation to each other and to the organism as a whole. So long as the growing cells are subject to this normal restraining influence—which has nothing to do with nerves and blood-vessels, themselves integrated structures—they develop in a regular and orderly manner, in accordance with the specific hereditary tendency of the whole; but when the restraining influence is modified or withdrawn, their potential reproductive activity may become actual. The outcome of cells abnormally set free depends chiefly upon the degree of emancipation. In the higher animals this is never complete, and their cells are always more or less differentiated; hence, instead of new individuals, only such structural modifications as neoplasms are produced. Under these circumstances, wherever there is a sufficient supply of nutritive materials a neoplasm will arise. The persistence of the excessive proliferative activity—the essential feature of malignity—is due to the awakening of cell-potentialities of the highest order. J. G. Adami[1] believes that the fundamental phenomenon underlying the development of cancerous or other neoplasms is the assumption of a habit of growth, of rapid cell-division, by certain cells independent of external stimulus. The latent capacity for such growth is illustrated by the reproduction of the whole plant or animal from a fragment of begonia leaf or of a hydra respec-

[1] Mont. Med. Jour., Feb., 1896.

tively; among crustacea, by the reproduction of single parts. In man chronic irritation of moderate intensity causes a proliferation of cells of highly organized tissues with the assumption of an embryonic type; and this at times doubtless passes on into carcinoma. The only distinction between the inflammatory and cancerous growth is that in the former the abnormal growth ends when the cause of irritation is removed, while in the latter the cells have gained the habit of unrestrained growth from frequent and rapid multiplication in a somewhat embryonic state. Among the factors that may possibly be concerned in the production of the habit of growth are increased nutrition, modified nerve-control, chronic irritation, and parasitic action. Parasites may at least be one cause by producing chronic irritation. After the climacteric, when the absorption of certain components of various tissues occurs, other portions receive increased nourishment; and especially when by injury, possibly years previously, a certain amount of instability has already been introduced, we have a condition particularly favorable to irregular and subadult cell-growth. Since benign growths may pass into malignant, all neoplasms should be removed as soon as possible. C. F. Martin[1] argues that irritation alone cannot be the cause of cancerous growths, or else they would occur more frequently. In favor of the theory of parasitic origin he says that parasites frequently cause cell-proliferation independent of inflammatory conditions, as shown by the lymphomata of typhoid and the enlarged spleen of malaria—a proliferation analogous in general features to carcinoma; that they produce metastases, as does carcinoma; that they often select certain cells for their habitat, as blood-cells in malaria, multinuclear leprosy-cells in leprosy, and giant-cells in tuberculosis, while the hypothetic cancer-parasite may equally well choose epithelium. Finally, certain parasites, coccidia, cause in the bile-ducts of rabbits an increase of epithelial and fibrous tissue closely resembling malignant adenoma of the rectum. F. J. Shepard[2] considers local irritation the most potent of many exciting causes of carcinoma. J. P. Warbasse[3] says that Cohnheim regarded as the cause of the formation of tumors a failure or irregularity in the embryonal tissues, showing that in normal development, and indeed very early, certain groups of cells, instead of continuing to grow, remain latent and later develop into tumors, this development occurring when the blood-supply is increased, the resisting power of the surrounding tissue diminished, or under some other condition. A great obstacle to the acceptance of this theory has been that these hypothetic separated cells cannot be discovered, and experiments have done little to support the theory. Roux, however, discovered separate colonies of cells in the middle, more rarely in the inner, embryonal layer of frog embryos, sometimes in large numbers scattered among the other cells. Late impregnation was the most important condition for their development. Roux's observations are not complete, for he could not say what would become of these cells, and whether a tumor would have developed from each one; but they taught the possibility of a separation of cells, as Cohnheim had assumed. Barfurth observed that by puncturing and

[1] Mont. Med. Jour., Feb., 1896. [2] Ibid. [3] Ann. of Surg., Jan., 1896.

turning in the ectoderm of the gastrula a growth of cells very like a dermoid took place. Here also we do not know what such a group of cells would do in a fully-developed embryo. From the observations of Ribbert[1] and others the writer concludes that tumors originate before and after birth from a partial or complete separation of cells or groups of cells from their organic connections, traumatism being an influence capable of causing the epithelial metastasis. The separated cells, no longer subject to the restraining influence of their normal connections, and still receiving an adequate nourishment, grow and form tumors which, according to the size and organization of the separated mass, correspond in general structure with the organ from which they sprang, sometimes more, sometimes less. Ribbert's theory of the origin of carcinoma does not necessitate the lying dormant of carcinomatous cells for 40 years, but explains how diseased or normal epithelial cells may become separated by trauma, inflammation, or other causes, and continue to grow surrounded by connective tissue and in easy access to the lymphatic channels. It may be regarded as a continuation and elaboration of Cohnheim's theory.

The Parasites in Uterine Carcinoma.—Müller[2] reports careful examination of the carcinoma-cell contents for parasites in 21 cases of uterine carcinoma. The result was that in 1 case of carcinoma of the posterior lip of the cervix he saw 3 cyst-formed bodies which were pale and glassy, with a colorless membrane. They are minutely described and shown in drawings. Smaller cyst-like bodies with and without contents are also shown. Besides these, in the same case, intracellular bodies without a capsule were found. These parasites, according to Müller and others, are ameboid organisms. The encapsulated is probably the more constant form of intracellular ameboid. He believes that their presence cannot be positively proved in fixed preparations. They must be seen in living tissue in pure culture. Braithwaite[3] states that out of a very large Jewish population in Leeds in not one Jewess has he ever met with carcinoma of the genital organs, whereas it is extremely common among Christian women. The inference is that the microorganism, if such exist, is introduced by the husband concealed beneath the prepuce.

The Anatomy of Carcinoma Uteri.—Veit[4] makes some important practical suggestions growing out of his more recent anatomic studies of this subject. He does not think that sufficient attention has been paid to the different varieties of carcinoma in the giving of a prognosis as regards recurrence after hysterectomy, nor is he inclined to agree with Winter in his statement that a considerable proportion of such recurrences are due to the infection of healthy raw surfaces during the operations. He divides carcinoma of the cervix clinically into those cases in which the disease is situated in the portio or in the cervical canal, and those in which it appears in a nodular form in the cervix, or as disease of the corporeal endometrium. Primary nodules in the cervix originate in the connective tissue, and are now regarded as endothelioma. As regards extension of the disease, Veit has often found cancer-cells in the

[1] Deutsch. med. Woch., 1895, Nos. 1–4.
[2] Arch. f. Gynäk., Bd. xlviii. H. 2, 1895.
[3] Lancet, June 29, 1895.
[4] Centralbl. f. Gynäk., 1895, No. 24.

lymphatics of the broad ligaments; when these infected vessels are divided during operation it is natural to infer that they form foci from which a rapid recurrence takes place. The latter form of recurrence is characterized by the fact that the metastatic deposits present the same histologic structure as the primary disease, and that they rapidly invade the deeper tissues. The simultaneous appearance of two apparently independent primary carcinomatous nodules can usually be explained by referring the more deeply-seated one to secondary infection.

Varieties of Uterine Carcinoma.—A case of primary horny epithelioma of the corpus uteri—a condition quite distinct from the squamous epithelial new-growth described by Zeller as ichthyosis uteri—is recorded by Flaischlen,[1] and cases of secondary growth by Emanuel,[2] and Rosthorn.[3] Flaischlen classifies the disease in three categories: (1) The superficial extension of a cervical cancroid over the inner surfaces of the uterine body; (2) The metastases of squamous epithelioma from a primary cervical carcinoma; (3) The development of a primary squamous epithelioma on the endometrium of the uterine body. As regards the origin of both of the secondary forms, all authors agree that they develop from the superficial squamous epithelium. In the development of this form of carcinoma the glands of the endometrium are undisturbed. Of the greatest interest is the primary development of squamous epithelial carcinoma in the corpus uteri. In addition to the present report only 3 cases are to be found in literature (Piering, Gebhard, and Löhlein). As a rule, primary epithelioma of the uterine body appears in women who have passed the menopause. Flaischlen's case occurred in a woman 54 years of age, Emanuel's case in one 44 years of age, and Rosthorn's case in one 41 years of age.

Malignant adenoma of the corpus uteri has been exhaustively studied by Beyea [4] (see Plate 4) and Stone.[5] Beyea states that there is considerable diversity of opinion as regards the nomenclature of this disease, whether it should be regarded as a form of adenoma or a carcinoma, since in many instances it first appears as an atypical adenoma, and as the disease advances it resembles glandular carcinoma. Its definite character as malignant adenoma was first described by Schröder in May, 1876, at a meeting of the Berlin Obstetrical and Gynecological Society. In March of the same year Martin saw and operated upon his first case. Goodell refers to it as villous degeneration of the endometrium; Ruge and Veit, as glandular carcinoma; Ziegler, as adenoma destruens; Wyder, as a malignant adenoma. Williams definitely separates malignant adenoma and carcinoma. A number of cases of malignant adenoma have been referred to by Winckel, Gusserow, and Schröder; Martin has operated upon 19 cases; Hofmeier has reported 15 cases; and Schönheimer, 1 case; Goodell, Mann, and Duncan have reported cases as villous degeneration; Coe has seen 4 cases, and in the past $2\frac{1}{2}$ years Beyea has seen 4 cases. Stone also reports 4 cases. Its relative frequency as compared with other forms of

[1] Centralbl. f. Gynäk., No. 22, 1895. [2] Ibid. [3] Ibid., No. 15, 1895.

FIG. 1.—Malignant adenoma (advanced). FIG. 2.—Benign adenoma. (From drawings furnished by Dr. H. D. Beyea.)

primary malignant disease cannot be estimated, but it is very rare. Like alveolar carcinoma, it occurs more often in multiparous women and in the postclimacteric period. It may, however, be seen as early as 20 years. Stone states that it usually occurs later in life than carcinoma, and lasts longer without causing cachexia. It is not so apt to give metastasis. Pain and discharge, according to Stone, are not such prominent symptoms in adenoma as in carcinoma, but uterine enlargement is more marked. Histologically, it appears as a benign adenoma that has undergone malignant degeneration. The gland-spaces are very much enlarged, very irregular, and are frequently seen to break through into other gland-spaces. The columnar epithelial cells are attached to the stroma as a rule, and they are often converted into cuboidal or even squamous cells, which may frequently be seen filling up a gland-space; they, however, never infiltrate the interstitial or stroma tissue. The disease extends to, and appears to progressively destroy, the muscle-wall by atrophy or perhaps fatty degeneration. It persistently progresses as an atypical glandular epithelial type of disease. An early diagnosis from the history of the symptoms and a physical exploration cannot be made, but Beyea states that at least 90% of the cases can be diagnosed by microscopic examination, but that the pathologist should be thoroughly familiar with the histologic appearance of every other disease that affects the corporeal endometrium.

Diagnosis of Carcinoma.—Most important in the prognosis of uterine carcinoma is the early recognition of the disease. Kessler[1] calls attention to the fact that while carcinoma of the uterus if attacked in the early stage can be cured by a radical operation, the mortality of which is only 5%, as a matter of fact not over 15% of those thus treated survive, because the patients apply too late to be cured. Statistics show that in the majority of the cases well-marked symptoms have been present for a year or more before the disease was recognized, and that in 50% of these the family physician failed to make a vaginal examination, which should never be omitted in the case of any woman 45 years of age or upward with atypical hemorrhages.

Neumann[2] reports a series of 1000 cases of postclimacteric hemorrhage from the genital tract, collected in the Schauta Clinic in Vienna. In more than half of the cases (54%) the hemorrhage was due to carcinoma of the cervix. Neumann believes that when chronic and severe metrorrhagia occurs in a woman who has passed the menopause, and she is failing in health and becoming anemic, a diagnosis of carcinoma of the corpus uteri can be made almost with certainty, provided there be not carcinoma of the vaginal cervix. Robb[3] claims that carcinoma of the cervix occurs more than 50 times as often as carcinoma of the corpus uteri. He regards an elevated area differing a little in color from the sound mucosa, and tending to bleed freely upon the slightest touch, as a suspicious condition, and, if this be persistent, the uterus should be removed. He does not have faith in the microscopic examination of the mere

[1] St. Petersburger med. Woch., 1895, No. 37.
[2] Monatsh. f. Geburtsh. u. Gynäk., Bd. 1, H. iii., 1895.
[3] Am. Gyn. and Obst. Jour., Sept., 1895.

scrapings of the curet, for he states that it is possible to have an increase in the number and size of the glands, and even the presence of more than one layer of epithelium, without any coexisting malignant disease. It is only when the subjacent tissues have been invaded by the disease that the diagnosis becomes sure. To determine this, a portion of the cervical tissue must be cut out and examined microscopically. Thornton[1] lays special stress upon the characteristic sacral pain so commonly present, which, according to Griffith,[2] is not only not relieved when the patient lies down, but usually becomes worse or at least less bearable. It is also referred more frequently to the region of the trochanters than is pain due to other causes. Sinclair[3] emphasizes the diagnostic importance of the extreme friability of carcinomatous tissue as exemplified by the use of the curet. If the tissue be not malignant, the curet will only make the parts bleed.

Upham[4] heartily endorses Cullen's formalin method for the rapid diagnosis of uterine scrapings. The method is as follows: The specimen is frozen by carbonic acid or ether, and cut; then (*a*) place the frozen section in 5% aqueous solution of formalin for from 3 to 5 minutes; (*b*) leave in 50% alcohol 3 minutes; (*c*) in absolute alcohol 1 minute; (*d*) wash out in water; (*e*) stain in hematoxylin for 2 minutes; (*f*) decolorize in acid alcohol; (*g*) rinse in water; (*h*) stain with eosin; (*i*) transfer to 95% alcohol; (*j*) pass through absolute alcohol, then through either creasote or oil of cloves, and mount in Canada balsam. Upham records 6 cases in which the diagnosis of malignancy was made by this process.

Treatment of Carcinoma.—[The abdominal route has been steadily growing in favor among the American gynecologists, to the exclusion of kolpohysterectomy, notwithstanding the efforts of some men to substitute for both the improved combined vaginoabdominal method, which is merely the old Freund operation in a new guise, and which is a far more dangerous operation than either of the others. The points that have been offered in support of the abdominal route are the greater ease with which it may be accomplished, the smaller amount of mutilation, the field of operation being left in a much more satisfactory condition than after the vaginal operation; there is no need of drainage in the abdominal operation because of the complete closure of the peritoneal cavity, while after vaginal hysterectomy the abdominal cavity cannot be entirely closed with safety, and the drain extending through the vulvar orifice is a possible source of infection, and therefore a constant menace to the safety of the patient. Again, extrusion of the bladder through the vaginal route is a much more common sequence than ventral hernia after the abdominal operation.] Finally, as Fish[5] remarks, in some cases of vaginal hysterectomy complete ligation of the broad ligaments and the contained vessels cannot be done, and clamps must be used, with the attendant objections. The main objection to the abdominal operation is the greater immediate danger from shock. Martin[6] in an

ligament in sections, with double ligatures, as far down as the internal os, employing for the purpose Galabin's pedicle-needle—a blunt fully-curved needle with two large eyes—and sterilized silk (No. 5). The bladder is then

stripped off, and the vagina opened close to the anterior lip of the cervix by cutting upon a Wells's forceps introduced through the vulva. The uterine

arteries are then ligated and the uterus removed. The ligatures controlling the uterine arteries are drawn down into the vagina and a piece of gauze inserted. In all cases of cervical carcinoma in which the infection has extended

to the pelvic glands, in all cases of recurrence after hysterectomy, and in so-called inoperable cases, Pryor[1] advocates the ligation of both internal iliac arteries as a step preliminary to any other. He claims that the disease is

retarded by this procedure. Clark[2] is convinced of the inadequacy of any method of treatment of uterine carcinoma. He states that recurrence in slight involvement of the broad ligament results from cutting the broad ligaments too closely to the uterus and from not removing a sufficient quantity of the vagina. To overcome this error he advises, and has practised in 2 cases, the

PLATE 5.

Hysterectomy for cancer of the uterus. The peritoneum of one side of the pelvis is dissected off, showing the intimate anatomical relation of the bladder, uterus, uterine artery, and ureter. Bougies are inserted into the ureters, making them stand out as rigid tubes. The close relations of the uterine artery and ureter and the ureter and cervical portion of uterus are well demonstrated, showing the impossibility of a wide excision of the broad ligaments without the introduction of the bougies into the ureters (Johns Hopkins Hosp. Bull., July–Aug., 1895).

following method of abdominal hysterectomy (see Plate 5): (1) Bougies are inserted into the ureters under the local effect of cocain. (2) An abdominal incision is made of sufficient length to ensure free manual movement. (3) The upper portion of the broad ligament with the ovarian artery is ligated as near as possible to the pelvic wall; the vesicouterine peritoneum is divided around the opposite side, the bladder is pushed off, and the layers of the ligament are pushed apart, exposing the uterine artery. (4) *The uterine artery is dissected out for 2.5 cm. from the uterus beyond the vaginal branch, and tied.* (5) The ureter is dissected free in the base of the broad ligament. (6) The remainder of the broad ligament is ligated close to the iliac vessels and cut away from its pelvic attachment. (7) The dissection is carried well down below the carcinomatous area, even though the cervix alone seems to be involved. (8) The opposite side is treated in the same manner. (9) The vagina is perforated with sharp-pointed scissors, strong traction being made on the uterus with small volsella forceps, so as to pull the vagina up and make its walls tense; it is then ligated in small segments (1 cm.) and each segment cut as it is tied. (10) Iodoformized gauze is inserted from above into the raw space left by the hysterectomy; the vesical and rectal peritoneum are drawn over this with a continuous fine silk suture. (11) The pelvic cavity is irrigated, and the abdomen closed without drainage. There are three essential steps in this operation that differ from those now employed: 1. The introduction of the bougies, allowing a more extensive extirpation of tissue adjacent to the uterus without danger to the ureters; 2. The ligation of the upper portions of the broad ligaments and ovarian arteries, cutting them close to the pelvic walls, opening the two layers, and ligating before excising any tissue; 3. The excision of a much larger portion of the vagina than is usual. The uterine artery is ligated close to the pelvic wall, as the ligature will be less apt to contain carcinomatous tissue, the danger of hemorrhage is eliminated, and the broad ligament can be cut away close to its attachment. [The main objection to Clark's operation is the length of time required for its performance. It is impossible to complete the operation under two hours, and but few patients can withstand the shock of the prolonged etherization.]
